POLIOMYELITIS ANTERIOR AS AN EPIDEMIC DISEASE.*

By HENRY W. BERG, M.D.,

NEW YORK.

VISITING PHYSICIAN TO THE WILLARD PARKER AND RIVERSIDE HOSPITALS, ADJUNCT PHYSICIAN TO MT. SINAI HOSPITAL, INSTRUCTOR IN CONTAGIOUS DISEASES, COLUMBIA UNIVERSITY.

COMMENCING at the end of June of the summer of 1907, physicians in New York and surrounding cities saw a constantly increasing number of cases of acutely occurring paralysis in infants and young children. During July, August, and the early part of September the cases became so numerous that most physicians with family practice saw a few and some many cases. The occurrence of the disease was not limited to any class of society, affecting the children of the rich as well as the poor in equal proportion, cases occurring even among the children who were out of town in vacation resorts and were living under the best hygienic surroundings. Being in the city all summer, I had the opportunity to see twenty-five cases, by far the largest part being seen in consultation with fellow practitioners.

The clinical manifestations of the disease were in some cases those classically recognized as infantile spinal paralysis or anterior poliomyelitis. In many of the cases, however, the affection manifested itself, in its clinical symptoms, as a combination of the symptoms characteristic of anterior poliomyelitis and those of acute bulbar paralysis, giving the picture of Landry's paralysis or acute ascending paralysis, a combination which might well be termed pathologically poliomyeloencephalitis, although such a term would at this stage of my discussion be objectionable in that it indicates an involvement not of limited portions of the cord or brain, but a general inflammation of the cerebrospinal axis. To this group characterized by bulbar paralysis, in addition to the paralysis of the extremities, three of my cases belonged, and all of these died. The remaining cases were ordinary cases, corresponding in a general way to classical cases of poliomyelitis anterior, for the most part divisible into two groups, that is to say, cases which I saw less than seventy-two hours from the onset in which the fever was still present, while there was extensive paralysis, and cases seen equally early in the history of the disease in which the paralysis was more or less extensive, with no fever present at the time of my examination, and only a history of fever less than two days in duration. In so far these latter cases resembled in their histories ordinary sporadic cases of infantile spinal paralysis. The cases marked by a fever of long duration suffered from a paralysis of lesser extent than the cases in which the duration of the fever was short. One case in which the only muscles paralyzed were those supplied by the right facial nerve, resembling a Bell's palsy, I saw on the eighth day when the temperature was still 102°.

While I had seen in my experience many hundred cases of paralytic anterior poliomyelitis in hospital and outdoor services with which I was connected, I had seen but very few cases of poliomyelitis anterior in the acute inceptive stage, and these few had been sporadic cases of the disease; even the many cases seen in the paralytic stage had occurred not in epidemics, but as sporadic cases. This epidemic of this disease was the first one of which I had any experience. So much was I impressed by the three bulbar cares of which I have spoken—a new class in my experience, although common in the epidemic form of the disease—that I was led to suspect that epidemic poliomyelitis anterior is a radically different disease from sporadic poliomyelitis anterior, possibly differing as widely as epidemic cerebrospinal meningitis when compared with the various types of non-epidemic or sporadic cerebrospinal meningitis; differing indeed in etiology, pathology, clinical history, prognosis, and treatment. If this distinction can be maintained much that is confusing and contradictory in recent clinical and pathological studies of poliomyelitis anterior as compared with the older and equally comprehensive studies will be explained.

The recent pathological observations are almost exclusively studies of cases that died in epidemics of the disease, while the classical older conceptions are based upon autopsy findings in sporadic cases of the disease. As is well known, one of the accepted dicta concerning the sporadic disease is that it is very rarely fatal; hence the rarity of autopsies in the inception stage of such cases. In the epidemic form of the disease, on the other hand, not only in this but in all epidemics that have occurred, the disease has an appreciable death rate; so that Harbitz and Scheel of Christiania were able to study and report in epidemics occurring in Norway from 1903 to 1906, 19 autopsies. In 1903 there occurred 18 cases with 6 deaths; in 1904, 61 cases, with 12 deaths; in 1905, 719 cases, with 111 deaths; in 1906, 334 cases, with 34 deaths, in all 1,132 cases, with 163 deaths. These cases, although the disease is not accepted as communicable, were all reported to the State Board of Health. So that the death rate of the epidemic poliomyelitis anterior in the Swedish peninsula is about 15 to 20 per cent. Smaller epidemics in various countries have shown a similar death rate, and our present epidemic has probably been no exception. But, inasmuch as our Health Department classifies all cases of meningitis together in its mortuary statistics and since, furthermore, physicians are apt to have reported deaths due to poliomyelitis anterior under various diagnoses, it is not possible to determine the exact number of deaths due to this cause. Comparing, how-

*Read before the Medical Association of the Greater City of New York, December 16, 1907.

ever, the death rate from cerebrospinal meningitis (including simple meningitis and spinal cord diseases) for 1906, when there was no epidemic, and 1907, when the epidemic raged, during the months of August and September, when the death rate due to this epidemic would be at its height, we find:

Number of deaths due to meningitis under 25 years of age in Greater New York, August and September:		*Number of deaths due to spinal cord disease under 25 years of age in Greater New York during August and September:*	
1906	109	1906	40
1907	134	1907	44

While these figures do not permit of any deduction as to the death rate or size of this epidemic, owing to the conditions which the statistics represent, yet they do admit the deduction that there has been a considerable death rate in this epidemic, so that the literature of the epidemic type of the disease need no longer be reproached with a lack of pathological study, owing to a dearth of pathological material. But it would be an obvious *non sequitur* to affirm of sporadic poliomyelitis anterior the results of pathological and bacteriological studies based upon autopsies of cases of epidemic poliomyelitis anterior, particularly if further evidence can be given of the conception that the two conditions while correlated are radically different diseases. On the other hand, such a conception, if confirmed, might materially modify our prognosis concerning the duration of the paralysis in the epidemic cases, and this is by far the most important symptom in the cases which recover.

It has been accepted that, while in the sporadic cases the extreme paralysis of the stage of onset undergoes regression, hence the term regressive paralysis (Barlow), no case absolutely recovers with disappearance of all paralysis. In all cases a more or less extensive paralysis remains for life. On the other hand, in this epidemic in my limited experience—for this epidemic must have numbered two thousand cases in this section of the country—several times my prognosis as to the permanent nature of a part of the paralysis has not been confirmed. Two of the cases recovered entirely within six weeks, no obvious paralysis remaining. These and other points will serve to emphasize the importance of the clinical study of the epidemic as contradistinguished from sporadic cases of this disease, particularly in the light of the renewed interest aroused by the occurrence in this city of this the largest recorded epidemic of this affection.

The first reliable report of an epidemic of this disease, occurring in 1881, was that of Bergenholz in Umea. He reported thirteen cases. The first extensive epidemic was studied by Medin[1] of Stockholm, occurring in that city in 1885. Four of these cases were studied by Rissler[2] pathologically, the patients having died on the sixth, seventh, and eighth day of the disease, and one in the seventh week after the onset. Prof. Medin[3] reported a further epidemic in 1895. Medin described in all sixty-four cases. The next epidemic of any consequence occurred in Otter Creek Valley in Vermont and numbered about 160 cases described by McPhail.[4] No cases of this important epidemic came to autopsy, although there were deaths. Smaller epidemics without pathological study were described by MacKenzie[5] and by Painter[6] (38 cases). In Norway minor epidemics were recounted with careful autopsies, and clinical and pathological observations and studies by Bülow Hansen and Francis Harbitz.[7] Looft[8] and Leegaard,[9] who described 54 cases, gave a clinical account of two minor epidemics. Francis Harbitz and Olaf Scheel[10] of the University of Christiania, Norway, described the epidemics to which I have referred above, the only epidemics that approach in magnitude the recent one in this city, and presented us with a clinical and pathological study of the disease, which in its completeness and thoroughness is worthy of all rivalry.

In the Southern hemisphere the epidemic form of this disease is not unknown. It is interesting to note that here the cases occur during the summer months of those countries, namely, during December, January, and February. Thus Wade[11] of Sydney, Australia, described an epidemic of 34 cases. Litchfield, also of Sydney, describes 25 cases of the same epidemic. Etiological data obtained from a clinical study of these various epidemics yield very little. The main facts are that the cases occur during the hot and dry months of summer, July, August, September, and October. The two largest epidemics seen in this country, the one in Vermont and the recent one in New York, occurred during summer months of exceptional dryness. Through reports furnished from the office of Mr. E. H. Emery of the U. S. Weather Bureau, I find that during July, 1907, the total precipitation of moisture in New York was 1.18 inches, of which .55 occurred on July 20, the remainder being divided over the rest of the month. The average precipitation for July for 37 years past is 4.38 inches, July, 1907, having the lowest precipitation of any July in 37 years past, since 1871. During August, 1907, the total precipitation was 2.48 inches, the average for August for 37 years past is 4.53 inches. On the 11th of September there occurred .73 inches of precipitation, and from that time on the moisture was excessive.

In MacPhail's report of the large epidemic in Vermont, he noted that the season had been exceptionally dry, no rain falling during weeks, while the epidemic was at its height. Medin's epidemic occurred during July, August, and September. He does not mention, however, whether the months of both epidemics described by him were free from moisture. The criticism that the largest epidemics of this disease have occurred in seaboard cities and not in inland and dry countries, and that hence no importance is to be attached to the lack of precipitation coincident with the epidemic, is not valid, when it is recalled that children in dry climates habituated to certain limited variation of moisture and temperature become acclimated to these and will not be affected by conditions which would have a deleterious effect upon those not acclimated to similar variations.

The question of contagion, or rather the communicability of the disease, was studied in some of the epidemics, particularly in Norway and Sweden. Dr. Geiersvold, who studied the epidemic in Norway referred to above (Harbitz and Scheel), reported the results of his investigations to the Swedish government, by whom he had been commissioned for this especial work, and expressed the conviction that the disease was contagious, several families being stricken in the person of more than one member. Harbitz and Scheel agree with this view, although they acknowledge that in the city of Christiania a painstaking investigation failed to demonstrate any connection between the cases. In my own experience in the past summer I did not see more than one case in any one family, nor do I know of any instance in which multiple cases occurred in the same family, although I have heard

of such. Most of my cases were seen in the family practice of other physicians, the cases being in close contact with other children; and these were the conditions under which most of the cases were seen in the city. That under these circumstances no cases pointing to direct contagion should have occurred is strong if negative evidence that this epidemic disease is not contagious.

One peculiarity that stamps the epidemic form of the disease and distinguishes it from the sporadic form is the fact that it occurs in older children as well as in infants. Indeed, young adults have not been free from it. Children from five to eight years of age were not infrequently affected by it, although the vast majority of cases were in children under five, and very many of them infants. One of my cases which terminated fatally after three days' illness was a young girl eleven years of age with bulbar symptoms, which I diagnosticated as a case of acute ascending paralysis, the so-called Landry's paralysis. This case was seen in the hospital and came to autopsy. Another similar case with bulbar symptoms was that of a boy seven years of age, seen on the second day in consultation, and death on the fifth day. All my other cases were under five years of age. Dr. Geiersvold found both children and adults were attacked in the Norwegian epidemics. Of the 19 autopsies on recent epidemic cases studied by Harbitz and Scheel 8 were in adults. Other observations of epidemics found similar conditions with regard to adult susceptibility to the disease. This is a very important distinction between the epidemic and sporadic disease, which owed its name, acute infantile spinal paralysis, to the fact that the sporadic form of the disease was not known to affect adults.

The symptomatology of the epidemic type of this disease is very different in many respects from that of the acute stage in a sporadic case. The fever is of greater duration in the epidemic cases, it is a more prominent factor and is never absent in any of the cases, while sporadic cases frequently occur in which a healthy child has gone to bed at night and waked in the morning with the characteristic spinal paralysis. In all of my cases the fever was present and in most of them it endured many days after the paralysis had appeared. The temperature curve was slightly irregular, but not septic in character, however. Many of the children were delirious and semi-comatose, a condition from which they emerged very slowly. There was no vomiting except at the onset. There was hyperesthesia of all the surface of the body, and in many cases seen on the first, second, or third day there was some rigidity of the neck and spine. Even the paralyzed limbs could not be handled without pain. The patella reflexes were in most of the cases absent. The initial rigidity at the back of the neck soon gave way to a flaccidity of the muscles about the neck, in some cases, particularly those in which the muscles of the back were paralyzed. I saw several cases in older children (three to eight years of age). In some of these there was incontinence of feces and urine, symptoms that do not form a part of the history of sporadic cases of this disease in which the sphincters are never affected. Three of my cases had bulbar symptoms and died of symptoms due to the involvement of the hypoglossal, glossopharyngeal, and pneumogastric nuclei. One of these cases had a comparatively low temperature, mental condition absolutely clear, and yet total paralysis of all the extremities and muscles of the back, together with the muscles of deglutition and speech, and finally died of diaphragmatic and cardiac paralysis. In one or two of the cases in this epidemic there was a temporary, at least, analgesia (pin test) in some of the paralyzed muscles from which the patient recovered about the time when the fever disappeared, so that clinically in these epidemic cases symptoms are present, not met in the sporadic cases of the disease, presupposing for their explanation a general inflammatory disease of the cerebro-spinal axis, including nuclei in the pons and medulla, and longitudinally a more or less extensive myelitis not only of the anterior gray horns, but of the posterior gray horns, the white columns, the anterior and posterior nerve roots, and even the meninges (pia mater). Fortunately, and thanks chiefly to Harbitz and Scheel (op. cit.[10]), Bulow-Hansen (op. cit.[5]), Rissler (op. cit.[2]), and Leegaard,[12] we have many autopsies made on cases dying from epidemic so-called poliomyelitis anterior during the acute stage, with careful microscopic and macroscopic studies of the findings in the cord, brain, and all the other organs of the body, and in cases of Harbitz and those of Bülow-Hansen even bacteriological investigations made during life (lumbar puncture, blood cultures, etc.) and post mortem.

On the sporadic cases of the disease we have four autopsies made on cases dying during the acute stage of the disease, although such autopsies are extremely rare. In two of these the symptoms of acute poliomyelitis anterior complicated measles with bronchopneumonia, of which latter the children died. These were reported by Siemerling.[13] One case by Dauber,[14] an eight and one-half months' child, dead on the sixth day of the disease, and one case by Redlich,[15] a five-months'-old-child, dead on the ninth day, one case of Drummond and one of Goldscheider, sporadic cases of the disease in both which the original disease, pneumonia, was complicated by the paralysis I purposely exclude, because the death was due to the pneumonia, as in the cases of Siemerling, and, as in those cases, the infantile paralysis was a complicating affection, so that to consider them is superfluous. We have large numbers of autopsies on cases of sporadic poliomyelitis anterior dying months and years after the occurrence of the paralysis from some other disease in which the classical lesion of poliomyelitis anterior and secondary changes in the anterior nerve roots were found and nothing else, but such autopsies could not serve for comparison with autopsy findings in cases dying in the acute stage of a recent poliomyelitis anterior epidemica.

With regard to the findings in the sporadic cases. First, Dauber's case: Child of a physician, eight months old. Fever three days; paralysis on third day; death on sixth day. Autopsy showed poliomyelitis anterior acuta. Anterior horns most involved; slight changes in posterior gray horns, especially in columns of Clark. No changes in any other organ of the body. Second, Redlich's case: Girl, age five months; fever and paralysis simultaneously observed; death on ninth day. Autopsy—poliomyelitis acuta. Changes limited to the anterior gray horns (ganglion cells), round cell infiltration, and changes in the blood-vessels of the arteries of the anterior fissure.

Siemerling's two cases: One, boy two and one-half years old, died on the eighth day of the paralysis, which had been preceded by a pneumonia. Another, a boy eight months old; pneumonia a week, then paralysis and a few days later death. In both cases autopsy. Pneumonia. In the cord polio-

myelitis anterior acuta limited as in Redlich's case to the cord and in the same areas of the cord.

Let us compare these cases with some of those dying in epidemics of so-called poliomyelitis anterior.

But before considering these I must not neglect to explain why I have not included among the autopsies on non-epidemic cases of poliomyelitis anterior, the two thoroughly studied cases of Bülow-Hansen. These were all the more interesting in that the affected were two children, brothers, five and four years of age respectively, one dying on the seventh and the other on the fifth day of the disease. These cases were not seen during an epidemic. The autopsies showed in both children poliomyelitis anterior acuta, together with soft, large spleen, hyperemic kidneys, and the post-mortem changes in the intestinal tract characteristic of first week of typhoid fever, such as swelling of the mesenteric glands, intense hyperemia, and swelling of Peyer's patches throughout the small intestine. Large intestine normal.

Curiously enough, Bülow-Hansen based his entire study of the pathology and pathogenesis of acute poliomyelitis anterior upon these two cases; blind to the fact which his own extensive record of the autopsy findings reveals, namely, that he was dealing with two cases of acute, septic typhoid fever, with infection either of the typhoid bacillus or mixed infections in the cord and meninges. These cases occurred before the era of agglutination reactions (Widal) in the diagnosis of typhoid and before blood cultures were customary and frequent. He preferred to look upon these cases as cases of enteritis complicated by bronchopneumonia and poliomyelitis anterior acuta, or rather he considered the latter condition the disease and the enteritis and pneumonia complications.

The inception of the disease in both children was four days apart. The older child began with fever, diarrhea of thin watery stools, and cerebral and cord symptoms. Without the autopsy, one would be tempted to describe the condition as the typhoid state. The excellent account of the autopsy in both cases compels the diagnosis of typhoid. The signs of general infection in these two cases are marked, but unfortunately for those who would establish the view that sporadic poliomyelitis anterior acuta is an infectious disease, the port-mortem evidence that they were both cases of typhoid fever is also in my opinion self-evident.

We come now to the consideration of autopsy findings upon cases of poliomyelitis anterior acuta epidemica. The material we have to select from is considerable, for epidemic infantile paralysis, so-called, is frequently fatal, differing in this respect, as I have already noted, from sporadic poliomyelitis anterior. The best studied and most recent autopsies of this type of the disease are those of Harbitz and Scheel. The study includes 19 cases at necropsy, of which 13 were cases of acute poliomyelitis, including acute bulbar paralysis, 7 children and 6 adults. These cases died after two, three, four, and five days, one of each, and 8 in from seven to ten days. The authors state that in the nervous system the following changes were found: In the spinal cord, a diffuse infiltrating inflammatory process, closely related to the blood-vessels, chiefly in the anterior horns, but involving to a less extent the whole gray matter more or less extensively longitudinally through the whole cord. Inflammation could also be traced in the white matter and in the pia mater with its prolongations; this, however, was demonstrable only by microscopic examination. There was also a cellular infiltration consisting partly of small and large mononuclear lymphocyte-like cells, especially in the pia and white substance, while in the gray substance the cellular infiltration consisted partly of polymorphonuclear leucocytes. There was marked degeneration of the ganglion cells over large areas of the cord. They also state that the inflammation in the cord was more extensive than might be expected from the clinical symptoms, and in cases suffering only from symptoms of acute bulbar paralysis there was found extensive inflammation all along the cord. Occasionally the inflammation was hemorrhagic with small hemorrhagic cavities in the anterior gray cornua.

The inflammation of the pia mater on the cord and in the fissure was demonstrated opposite sections of cord, in which the cord itself was not involved, which Harbitz believes shows that the inflammation begins in the pia and extends to the cord along the vessels. The inflammation is most intense in the anterior gray horns because these are supplied by the largest vessels. There is, therefore, a meningitis which precedes the inflammation in the anterior gray horns. Indeed, the pia mater is inflamed around the medulla and pons, about the cerebellum, along the base of the brain and cranial nerves, and particularly along the Sylvian fossa, exceptionally even over the hemispheres. There was also in many of these cases inflammation of the brain substance, including the medulla and pons, the fourth ventricle and nearly all the cranial nerve nuclei. The white matter, however, was but very slightly or often not at all involved. In nearly all the cases examined, even those giving no bulbar symptoms, all the cranial nerve nuclei were attacked by the inflammation. As a rule the gray matter around the aqueduct of Sylvius with the third and fourth nerve nuclei were involved. The inflammation, however, was more intense in the cord than in the brain. There were even infiltrations in the cortex in some cases, particularly around the central convolutions. These were the severe cases that died, but even the milder cases which recovered but died of subsequent intercurrent disease, when examined showed (four such were examined) degenerated nerve tissue to a much greater extent than had been expected; changes were found in these cases not only in the cord, but in the medulla, basal ganglia, and in a few places in the cortex of the brain. The process even in the milder cases is therefore a general inflammatory one throughout the brain and spinal cord, and the pia mater of the brain and spinal cord.

It is obvious that the bulbar cases correspond closely in their symptom complex to cases of acute ascending paralysis, or what has been described as Landry's paralysis, as shown by Basoe.[16] Such bulbar cases have been quite frequent in our recent epidemic. They differ only in degree from the milder cases; the simple inflammatory changes in these go on to destruction and hemorrhagic infiltration of basic ganglia and bulbar nuclei in the severe bulbar cases. So that epidemic so-called poliomyelitis is in reality a general cerebrospinal leptomeningitis with anterior poliomyeloencephalitis. How different this from sporadic poliomyelitis anterior, which is exactly what the name indicates.

Except for the autopsy findings in the central nervous system, even in the epidemic disease there were no changes in other organs or viscera. There were no changes in heart or blood-vessels, no petechia, no changes in the lungs, liver, spleen, kid-

neys, mouth, nose, pharynx. There was no herpes or skin eruption, nor did I observe any such clinical manifestations in any of my cases. In four of my cases lumbar puncture was made, in two of the cases the fluid was carefully examined and proved sterile. It is true that Schultz[17] diagnosticated a case of poliomyelitis anterior, and found on lumbar puncture the meningococcus, but this was evidently a case of cerebrospinal meningitis epidemica. A similar case was reported by E. Tiedemann,[18] but Sicard,[19] who made such lumbar punctures in poliomyelitis anterior, reports normal cerebrospinal fluid, as did Triboulet and Lippman.[20] Cases observed in other services at Mt. Sinai Hospital, particularly the children's service, have yielded, I am told, sterile fluid on lumbar puncture. Bülow-Hansen made extensive bacteriological examinations on the cord and meninges post mortem. As I have already stated, I consider the cerebrospinal lesion in his cases as secondary to typhoid fever. But it may be of interest to know that he found no microorganism, either in cover glass preparations or cultures from the substance of the spinal marrow. No bacteria or bacterial emboli were found in crosssections made at numerous levels in the spinal cord. The cerebrospinal fluid obtained by lumbar puncture from one of his cases was sterile, cultures made from it were negative, and animals injected with the fluid suffered no pathological change.

It appears, then, from what has been said concerning the differences between sporadic poliomyelitis anterior and so-called epidemic poliomyelitis anterior, or, rather, as I think it should be termed, epidemic meningomyeloencephalitis, that the two conditions are radically different diseases; the latter including among its extensive neurological lesions the pathological changes characteristic of sporadic poliomyelitis anterior. The clinical manifestations of the two diseases differ as markedly as is necessitated by the widely different pathological changes characteristic of each. The two conditions, moreover, differ in their morbidity, in the ages of the patients for which each of the conditions has a predisposition, the sporadic disease being found in children almost exclusively, the epidemic disease affecting adults and children. They probably differ, moreover, in a very important characteristic, for sporadic poliomyelitis anterior cannot be considered an infectious disease, while epidemic meningomyeloencephalitis may be, although positive proof of its infectious nature is still lacking.

The term infectious disease, originally introduced by Virchow, is intended to include such diseases as are caused by the activity in the body of minute organisms, capable of unlimited reproduction, or their toxins, such organisms or their toxins or both being disseminated through the body in the various organs and giving rise to general symptoms, such as fever, etc., as signs of the general infection. This does not exclude the classification among the infections of those diseases in which the pathogenetic organisms or their toxins are unknown, for most of the infectious diseases, even the most contagious, belong to this class. But, on the other hand, in addition to the local lesion and the fever, there must be general symptoms, indicating the more or less general dissemination of the organisms and their toxins by means of the blood-vessels and lymphatics. So that in an infectious disease, in addition to the local and deciding lesion and fever, signs of infection in other organs of the body, such as the spleen, liver, kidney, heart, blood, etc., should occur. In sporadic poliomyelitis anterior we have only the local lesion and the temporary fever. The picture could be reproduced on a non-infectious basis. For instance, in status epilepticus lasting some hours the patient almost invariably has fever with the convulsions, due to irritation of the fever centers in the brain; and yet the condition is not an infection.

It is evident that the conception of an infection requires more than fever and a local lesion; even the epidemic character of an affection does not necessarily classify it among the infectious diseases, but in sporadic poliomyelitis anterior this latter characteristic is entirely absent, and it appears more logical, if the epidemic cases are to be considered as a different disease, to follow the teachings of that astute observer, Charcot, and look upon the changes in the anterior gray horns in the sporadic cases as primary, and the vascular and other inflammatory changes as secondary.

It is interesting to note that lesions similar to sporadic poliomyelitis anterior have been produced by positively noninfectious causes. Thus C. F. Hodge[21] showed that in animals the ganglion cells of the spinal cord suffered a vacuolation and a shrinkage of the cell body, with even a greater diminution in the size of the nucleus as the result of the prolonged action of weak electrical currents. In the study of the effects of electric currents of high potential, Mills and Weisenberg[22] report an interesting case of a typical bulbar paralysis following a shock of 1,000 volts two days before. Dr. Mills and S. W. Morton saw a case of bulbospinal paralysis or myasthenia gravis in the person of a lineman 30 years old, employed in the Philadelphia Electrical Bureau, apparently due to frequently repeated electric stimuli, which the patient had suffered in the pursuit of his occupation for a long period of time.

As to epidemic meningomyeloencephalitis, that is apparently an infectious disease; the causative factor, be it toxin or organism, is unknown. I say apparently infectious, not only because accompanied by fever and because it occurs in epidemics, but chiefly because the lesion is general throughout the cerebrospinal nerve centers. This notwithstanding the fact that but few well-authenticated cases of this epidemic disease as a primary disease have been reported in which concomitant inflammatory disturbances of other important organs were found.

In conclusion, then, I reiterate the belief that sporadic poliomyelitis anterior is entirely distinct from the so-called epidemic poliomyelitis anterior, more properly designated, as I have suggested above; that the sporadic disease is not infectious, and that the epidemic disease is in all probability infectious, but not contagious.

BACTERIAL VACCINES AND CURATIVE SERA.*

By CHARLES BOLDUAN, M.D.,

NEW YORK.

BACTERIOLOGIST, RESEARCH LABORATORY DEPARTMENT OF HEALTH OF THE CITY OF NEW YORK.

The discovery of diphtheria antitoxin in 1893 by Behring marked the beginning of the search for specific remedies, especially for specific antisera, and it was not long before a number of such sera were produced and employed clinically. The use of sera for specific therapeutic purposes was very attractive, because it was possible to have some animal, like the horse, manufacture the antibodies, and one needed then merely to transfer the animal's immunity to the patient by injecting some of the animal's serum.

You probably all know that, according to Ehrlich's theory, the antitoxin is nothing more than thrust-off side chains or "receptors" of the susceptible cells. These receptors, circulating in the blood, encounter the invading toxin, and by combining with it prevent it attacking the body cells. It is obvious that such toxin as has already combined with the cells cannot be neutralized by the antitoxin. Hence the antitoxin should always be given as early as possible and in sufficient doses. In desperate cases seen late, the antitoxin should be given in a massive dose intravenously. This method is perfectly safe if attention is paid to asepsis, and it may be the means of saving a life that would otherwise be sacrificed.

The clinical success of diphtheria antitoxin is now no longer open to question. Statistics prepared by the writer,[1] from large cities in this country and Europe, show that a marked decline in the diphtheria mortality coincides with the introduction of diphtheria antitoxin, and that this decline has continued with the more extended use of the remedy.

Most of you are aware that the antitoxin for tetanus has not achieved anywhere near the success of the diphtheria antitoxin. And you may also know that in laboratory experiments on test animals tetanus antitoxin is uniformly effective. The reasons for this difference are mainly two. In the first place, the diagnosis in tetanus is not made until the onset of the tetanus symptoms, that is, not until the tetanus toxin has entered into so firm a combination with the susceptible cells that no amount of antitoxin will prevent the toxic action. In diphtheria, fortunately, attention is usually called to the disease at an early period, owing to the symptoms of mechanical irritation, and before very much toxin has attacked the body cells. The other reason for the failure of tetanus antitoxin is that the toxin has so strong an affinity for cells of such vital importance, those of the central nervous system. There is, however, a distinct field of usefulness for tetanus antitoxin, and its use here should become more general. I refer to the value of prophylactic injections in cases in which tetanus infection may be likely. This includes particularly the Fourth of July wounds, which formerly were often followed by tetanus. Since the more extended use of the antitoxin in these cases, the number of deaths from tetanus after such accidents has markedly diminished. Thus in New York, where we formerly had a considerable number of such cases after each Fourth, there was not a single one after the last Fourth. Too much stress must not be laid, however, on Fourth of July wounds. There are many other crushed and dirty wounds into which earth has been ground which should be considered in this connection. If tetanus antitoxin is used in these cases the results are just as successful as those in our animal experiments.

Following the researches of Nuttall, Buchner, and especially of Pfeiffer, considerable work was done with specific antisera in cholera, typhoid fever, and a number of other diseases. These sera were bactericidal, that is to say, they *killed and dissolved the bacteria* against which they were specifically directed. Clinical trials soon showed, however, that these sera had little therapeutic value, and subsequently laboratory experiments disclosed a large number of difficulties in their practical application. It may be well to remind you that the destruction of bacteria by a bactericidal serum is brought about by the combined action of two substances. One of these, the immune body, is present only in the specific immune serum; the other, called the complement, is present in all sera, normal as well as immune, *while these sera are fresh*. The complement is a very labile body, and disappears from the serum on standing. For obvious reasons it is impracticable to use freshly-drawn serum clinically. When we inject the ordinary immune serum, therefore, we supply only the immune body and rely on the injected body to supply the complement. Unfortunately, it has been found that there is often a marked decrease of complement during infections, or as a result of wasting diseases, or in consequence of other depressing conditions such as overindulgence in alcohol. Yet it is just at this time that we may want an especially large amount of complement in the injected body to destroy the invading bacteria. Furthermore, no way has yet been found to increase the amount of complement in the organism. Another difficulty which may be encountered consists in the fact that with the bactericidal sera one can give too large a dose. There seems to be an optimum dose, and yet we have no way of determining what this dose shall be. Finally, it has been found in animal experiments that the species of animal from which the serum is obtained is also important. Thus in some instances an immune serum from a horse might not act in man, because apparently the harse serum fails to find a fitting complement in the human body. Whatever the reasons for these difficulties, the fact remains that the use of bactericidal sera for curative purposes has not been attended with any marked success. They have, however, been used with some success in immunizing against infection,

* Read, by invitation, before the Medical Association of the Greater City of New York, December 16, 1907.

and they are still used in what is called the "combined method" of immunization.

In the past few years it has become more and more apparent that the limitations of serum therapy are, for the present at least, almost insurmountable. Attention has therefore again turned to treatment by active immunization. Perhaps the best known examples of active immunity are the protection naturally conferred by an attack of scarlet fever, or measles, or smallpox, or the protection artificially produced against smallpox by vaccination, against rabies by the Pasteur treatment, or against anthrax by means of bacterial vaccines.

The scientific foundation for active immunization was laid by Pasteur. He showed that a mild attack of an infection, brought about by the use of an attenuated (weakened) virus, protected against subsequent infection with a strong virus. His first experiment was most dramatic. He injected half of a flock of sheep with an attenuated anthrax culture, and then, two weeks later, injected all of them with a virulent culture. All of the sheep not previously injected died, while not one of the others was even dangerously sick.

It was perhaps only natural, in view of his discoveries in fermentation, that Pasteur should have believed that the production of immunity required the action of the living virus. He therefore vigorously combated the idea that immunity could be brought about by means of dead virus, or of lifeless products of growth of the virus. Touissant, as far back as 1880, had held out for the latter possibility. The imperfections of his technique were such, however, that his views were not accepted. To Salmon and Smith of this country belongs the honor of first clearly demonstrating the possibility of immunization with dead cultures.

Active immunization, then, can be carried out in several different ways:

(1) By means of living cultures of the virus. Usually the cultures are attenuated, but there are some exceptions.

(2) By means of dead cultures of the virus. The cultures can be killed either by heat or by the use of chemicals.

(3) By the so-called "combined method," *i.e.* by first administering a dose of the specific immune serum and subsequently the virus. This method has been used in typhoid fever, cholera, and plague.

(4) By means of the products of autolysis of the cultures. This has also been used in typhoid fever, and seems to possess certain advantages over the use of native cultures.

(5) By means of various combinations of the preceding methods.

The attenuation of the virus, as mentioned above, can be accomplished in a number of ways. Thus, by drying, as is done with rabies virus in the Pasteur treatment. Or by growing the virus at a temperature unsuited for the development of virulence, as is done in the case of anthrax; or by passing the virus through a less susceptible animal, as is done in vaccination against smallpox; or by means of chemicals such as the addition of iodine solution to diphtheria toxin, as was formerly done by Behring; or by means of heat, as was also formerly done with diphtheria toxin.

The choice of these various methods of immunization depends on the nature of the infecting virus. With some infections dead cultures apparently are able to cause the production of full protective powers, while in other infections the body seems to require a greater stimulus. In these, the use of attenuated living cultures may bring about the desired immunity. Finally there are infections in which nothing short of fully virulent cultures seems to bring about the development of sufficient immunity. In these cases it is necessary to first prepare the way by the use of dead or of attenuated cultures.

At first active immunization was applied only to prophylactic treatment. The first to attempt to use this method in curing an infection already in progress was Koch. This was his tuberculin treatment of tuberculosis. While the prophylactic use of active immunization is usually easily understood, there often seems to be some difficulty in understanding how active immunization can accomplish anything in the curative treatment of an existing infection. As a matter of fact, we know that it does. The following are some of the explanations:

If the body is being ravaged by an infection, for example with typhoid bacilli, it is possible that the virulence of these is so great that the body cells are unable to produce any antibody against them. By immunization with dead or attenuated cultures of the bacteria, however, it may be possible to accomplish this. In the case of rabies our injections of virus into the more indifferent (*i.e.* less vital) tissue of the abdominal wall causes a production of antibodies possibly by that tissue, before the original infection has a chance to attack the more vital central nervous system. In the case of chronic infections, such as acne, multiple boils, joint tuberculosis, etc., we may assume that these do not tend to heal because there is insufficient absorption of bacterial substances to cause the development of antibodies. Or it may be that substances given off by the body cells immediately around the focus of infection combine with and change the bacterial substances so that these no longer stimulate antibody formation. In these cases, then, our injection of bacterial vaccine would supply this lack and so cause the development of antibodies.

The treatment of infections by means of active immunization has been greatly stimulated by the work of Wright,[2] who has published favorable results in a large number of infections. It may surprise many of you to hear that already several hundred thousand persons have been actively immunized against cholera, and that large bodies of troops have been immunized against typhoid fever. Until recently the method has found application particularly in the prophylactic immunization of persons liable to be exposed to infection. At the present time, however, owing largely to the efforts of Wright, the method has come to be used for curative purposes, *i.e.* for infections already in progress. That author has clearly formulated the conditions in which he thinks this form of treatment is indicated, and he has also devised methods for the more exact determination of doses than were formerly in use. There is no doubt that the possibilities of active immunization have not yet been sufficiently investigated, and Wright deserves great credit for his efforts in behalf of this mode of treatment. In this connection I may call your attention to the recent publication by Richardson,[3] on the treatment of typhoid fever. By using certain bacterial vaccines prepared after the method of Vaughan, he found that the typhoid process was apparently made longer but milder, and by continuing the treatment into convalescence the liability to relapse was diminished.

The advantages and disadvantages of active and of passive immunization may be summarized as follows:

Active immunization is usually more effective, more lasting, and is a general immunity, not merely one particular kind. It is slower, sometimes difficult to bring about, and may involve some risk to the patient.

Passive immunization is often ineffective, is often merely a special kind of immunity, and does not last long. It is instantaneous and convenient, and involves practically no risk to the patient.

A word now as to the term "bacterial vaccines." These, of course, have nothing to do with the real vaccine obtained from calves and used against smallpox. There is nothing of the cow, vacca, about them. The French have long used the term vaccin to denote any virus which is used for immunization, and that is the sense in which the term "bacterial vaccine" is now used. In other words, the material used for immunizing, whether this is a suspension of living or of dead bacteria or the autolytic products of culture growth, is spoken of as a "bacterial vaccine." A commercial firm has introduced the term "bacterine" for these preparations, and but for the fact that this is a copyrighted name, this designation would have been preferable.

In the use of bacterial vaccines, one must constantly keep in mind the nature of the bacterium with which one is working, and the kind of immunity one wishes to bring about. Everything depends on the way in which the vaccine is prepared. With bacteria making considerable quantities of a toxin, it will be necessary, if we wish to immunize against this toxin, to grow the culture for the requisite length of time and under the proper conditions for producing the toxin. In the case of bacteria possessing certain endotoxins, it may be necessary to let the cultures autolyze, so as to set these substances free. On the other hand, we may wish to use these bacteria for producing a specific agglutinating serum. In that case we often try to avoid injecting these toxic substances. Our entire procedure might then have to be quite the reverse of what I have just indicated. In immunizing with the tubercle bacillus, it is well to remember that this organism is encased in a peculiar waxy covering which largely prevents the body fluids from acting on it. Koch therefore crushes the bacilli so as to secure immunizing substances against the entire bacillus. Originally he sought to attain the same result by growing the cultures in a 5 per cent. glycerine broth and subsequently evaporating the filtrate to 1/10 its volume. This extract is now known as "old tuberculin," and is extensively used for diagnostic purposes, especially in cattle. It is also used in humans, but care must be exercised in selecting the cases and in the dosage. It is probable that the technique recently introduced by Pirquet[4] and subsequently modified by Calmette[5] will lead to the more extensive employment in the diagnosis of tuberculosis in humans.

Pirquet's method consists in making a fine scratch in the skin, and then rubbing a little old tuberculin into this. If there be a tubercular infection this will be followed by a characteristic induration or even vesiculation, commencing about twelve hours after the vaccination. In Calmette's method, the so-called "ophthalmo-diagnostic" test, a 1 per cent. solution of the dried alcoholic precipitate of old tuberculin is dropped into the eye under aseptic precautions. The first symptoms of a reaction appear in from three to twelve hours in most cases, but may be delayed twenty-four to forty-eight hours, and continue for a week. The presence of a reaction is indicated by a scratchy feeling, secretion, and redness of the inner canthus, caruncle, or lower lid, which may increase and include the entire conjunctiva with edema of the lids. Grünbaum,[6] Cohn,[7] Squire,[8] Comby,[9] Baldwin,[10] and many others have published favorable results with the ophthalmo-diagnostic test.

Wright's method of preparing a staphylococcus, typhoid, or streptococcus vaccine, is as follows:

Several streak slant agar cultures are planted and incubated for twenty to twenty-four hours. The cultures are then washed off with normal salt solution, using from one to several c.c. for each culture. These suspensions are next heated to 55° C. in order to kill the bacteria, and are then standardized. By this is meant determining the number of organisms per c.c., for Wright always used definite numbers of bacteria in his inoculations. This standardization is readily accomplished by means of the method devised by Wright, which is as follows: From a finger prick a drop of blood is sucked up in a capillary tube to a mark made at any convenient point with a wax pencil. Next an equal amount of the bacterial suspension is drawn into the tube, allowing a tiny air-bubble to intervene. The two fluids are then expelled on a glass slide, and then thoroughly mixed by sucking back and forth a number of times. After this has been done the mixture is spread in the ordinary way of making blood smears. If these blood smears, after staining, are examined with a microscope having a ruled eye-piece it is a simple matter to determine the ratio of bacteria to blood cells. Taking the red blood cells as 5,000 million per c.c., one calculates the number of bacteria per c.c. In practice it is advisable to so dilute the bacterial suspension that the dose to be injected is contained in about one c.c. of fluid. Finally ½ per cent. of carbolic acid is added as a preservative. Such a suspension is a "bacterial vaccine." It goes without saying that the vaccines should be tested by means of cultures to insure sterility, and that contaminations should be excluded by means of microscopical examination.

So far as doses are concerned, these vary with different bacteria, and also according to the indications, opsonic or clinical. The ordinary dose for the staphylococcus vaccine is from 200,000,000 to 1,000,000,000 organisms; for the streptococcus it is from 50 to 75 or 100,000,000, and for typhoid from 750 to 1,000,000,000 bacteria. All the injections are given subcutaneously, and it is well to repeat the injections every three or four days.

The clinical results obtained by means of bacterial vaccines have varied. There seems considerable agreement on the part of most observers that certain localized infections, such as acne, multiple boils, etc., often do very well with this method of treatment. In the treatment of bone tuberculosis the results are not so harmonious, and in the treatment of general infections many failures have been reported. There is no doubt, however, that treatment by means of bacterial vaccines deserves more extended application.

Most of you are aware that Wright guides his bacterial vaccine treatment by means of the "opsonic index." This index is the relative phagocytic power of the patient's serum compared to the average of several normal sera. Without going into the technique of Wright's method, it will suffice to say that these determinations are very difficult to make, and are subject to a number of unavoidable errors. Experiments made by the writer[11] show that the results of duplicate or more determinations made of the same serum at the same time and under apparently identical conditions, frequently yield widely

divergent results. There is also often a considerable variation in the opsonic indices of several normal persons. Finally, the opsonic index and the clinical course of the disease do not always run parallel. A number of investigators have proposed modifications in the technique in order to overcome these inaccuracies. It is possible that in this way opsonic measurements may be obtained more in accord with the clinical data. However, the absence of parallelism referred to is not at all surprising to the student of immunity, for, after all, the opsonic indices measure only one element of the mechanism of immunity. When Gruber and Durham published their observations on agglutinins, the phenomenon was at once hailed and interpreted by many as measuring the degree of immunity possessed by the patient. The same error was made some time later, when the bacteriolytic substances were discovered. In both cases it was soon found that these were but experiments, of greater or less significance, of the complex phenomenon of immunity. It would certainly be surprising if the opsonic power were to prove the real measure of the degree of immunity. At the present time, therefore, the writer believes that opsonic measurements, made according to Wright's method, are unreliable, and should not replace clinical observations in guiding treatment by bacterial vaccines.

THE EARLY DIAGNOSIS AND TREATMENT OF PULMONARY TUBERCULOSIS.*

By JOHN H. PRYOR, M.D.,

BUFFALO, N. Y.

FORMERLY SUPERINTENDENT AND AT PRESENT TRUSTEE OF THE NEW YORK STATE HOSPITAL FOR THE TREATMENT OF INCIPIENT TUBERCULOSIS.

The unquestioned decrease in the death rate from tuberculosis during the last thirty years began before the discovery of the bacillus and the introduction of special direct methods of prevention. The decrease has been relative; that is, in proportion to the population. The actual annual morbidity from tuberculosis in this State has not diminished, but increased. Recent tremendous progress in the nature of sanitary reforms has been almost entirely responsible for the reduction in prevalency and mortality. Consumption continues to cause from 1/10 to 1/11 of all deaths, and the death rate rises and falls with the general death rate.

A successful crusade against consumption will be measured largely by a diminution in the proportion of deaths due to that cause and this result will depend largely on two factors: prevention and saving the lives of those who escaped protection. True, effective prevention is in its infancy. Thus far it has been more or less of a delusion. Little or nothing has been done in this State, excepting in New York City. There great activity is displayed in a comprehensive campaign against the greatest scourge of humanity, and the results may afford the best test of preventive measures to be found in the world.

Ultimately the problem of tuberculosis will have to be solved by the health officers. They have the power and should assume the responsibility. Only organization, effective plans, and continuous, not spasmodic activity, will win. Anti-tuberculosis societies may agitate and support, but the health officers must take the initiative and insure the enforcement of practical measures. Otherwise so-called education of the public by those who are clinically positive, and sometimes acutely, may arouse public sentiment, but not secure action. Of course, upon which comes the proper initiative to [illegible], full duty is apt to accomplish the most lasting good.

We cannot know the direct and most of the contributing causes of tuberculosis and not feel that it is preventible and unnecessary. We know that the disease can be detected early and that about eighty per cent. of those afflicted might recover if rational methods of relief were employed. There are about fifty thousand deaths in this State and the death returns show an annual loss of life of more than fourteen thousand. The vast proportion of these deaths occur between the ages of twenty and forty, when productive power and ability to provide for dependents is at its highest level. Science has not revealed a way of estimating the amount of physical suffering and distress caused by this malady, and, therefore, we estimate the wanton waste of precious lives as a loss of wealth to the State of about $70,000,000 annually.

If these facts are true, and we have told the public that they are true, why does the appalling carnival of suffering continue and the ghastly disgraceful death rate maintains its yearly record? The time to look for reasons seems to have arrived. In the first place we are learning that promises and predictions based on narrow views have not been fulfilled. Consumption has not been eradicated, and there is nothing to show that it will be in the near future. The problem is stupendous and multiform and must be attacked by broad methods. It does not involve a mere bacteriologic question, but a sociologic reformation. The slogan of battle, "sunlight and fresh air," will be changed to "food, sunlight, and fresh air." Eighteen meals of oxygen a minute must be accompanied by three square meals of food a day. The poor cannot live on air and sunlight, and if the cost of existing, not living, continues to increase, consumption will be given greater opportunity to attack the underfed.

But we can save time by two confessions: first, the public is not properly protected: second, the death rate is not diminished as it might be in an enormous proportion by the early recognition of the consumptive and the adoption of well known measures for relief. The responsibility for failure must fall largely on the physician, and the hope of any true progress must depend more on the education of the medical profession. The task is an unpleasant one, but an impartial examination of existing conditions justifies the frank consideration of undeniable facts

*An address delivered before the New York State Conference of Health Officials at Buffalo, October 17.

The public has been inoculated with phthisiophobia and hysterical fear has added hardship to affliction, but there are signs of returning sanity. There has been a deluge of literature and an unrestrained flux of garrulity designed to reveal how much we know about tuberculosis. Now, how much has the knowledge been applied and how much has it helped the consumptive? The consumptive is an anomaly in the practice of medicine, and prolonged neglect has made his woe in a manner unique. He is the only sufferer from any known disease who does not receive the full benefit of medical skill and knowledge, and consequently consumption is the saddest thing in the world.

The diagnosis of incipient disease is the transcendent requisite. It means everything to the patient, and yet the early stage is seldom recognized. Until recent years an excuse existed for failure to detect the invasion of tuberculosis. Little or no provision had been made for the care of the curable cases, and it may have seemed useless to promptly find the existence of disease, particularly among the poor. It was assumed that the patient was doomed and he may have received the last new remedy or he was treated on the appropriately styled expectant plan.

About four years ago this State established a hospital for the treatment of incipient tuberculosis at Ray Brook to provide for 200 patients. The opponents of State care for this class prophesied that the demand for relief would be so great that the State would be financially endangered. They insisted that provision for only 200 was a mere flea bite, and in that contention they were right. The largest population ever recorded at Ray Brook has been 145. There is room to-day for more patients. Furthermore, only about 50 per cent. of the inmates can be classified as incipient cases, and consequently an institution devoted to their exclusive care is less than half filled by those who strictly belong there. Of those accepted 40 per cent. on the report of examination made by State examiners are found to be moderately advanced or advanced on admission. Only one-tenth of the applicants for admission could be accepted because 9/10 of those recommended by physicians were too advanced.

The population of all the institutions in the State designed for the treatment of consumption shows that about one per cent. enter an institution at the time when the greatest number of apparent recoveries can be expected. After years of strenuous effort on the part of those interested in procuring promising cases for treatment, it is found that the combined average for a large number of sanatoria in this country is about 20 per cent. of really favorable patients. The vital importance of early recognition and treatment is strikingly illustrated by the tabulated results obtained at Ray Brook for four years. During that time 549 patients were admitted. Of this number 267 were in the incipient state, 145 moderately advanced, and 47 advanced.

Condition	Total Cases	Apparently Recovered	Disease Arrested	Improved	Unimproved	Died
Incipient...	267	219 82.9%	37 13.9%	5 1.87%	5 1.87%	1 Hemorrhage
Moderately advanced	145	32 22.06%	89 61.38%	14 9.65%	10 5.9%	
Advanced..	47	0	26 53.3%	11 23.4%	10 21.27%	

Thus of the incipient cases 82.0 per cent. apparently recovered and 13.9 per cent. were arrested. Of moderately advanced cases 22.06 per cent. apparently recovered and of advanced cases none apparently recovered. It is fair to assume that about 160 patients failed to recover because they were sent to the hospital too late. If there are 50,000 consumptives in this State and the average duration of the disease is about three years, there must be thousands of the afflicted at any given time who are in the early stages of the disease. I appreciate the chances for error in statistics due to personal equation and faulty technique, but imagine what an early diagnosis and vastly increased provision for proper care would mean in the Empire State! Rational care of the early case constitutes ideal and humane prevention. Remember, also, that every inmate is sent home with a liberal education. He knows how to take care of himself, the best his condition and environment will allow, and he ceases to be a source of any danger to his fellow beings. Every graduate is a teacher of hygiene and the gospel of fresh air. The consumptive has a right to insist on this chance. Why doesn't he demand it? Because he does not know, and generally is not told, that he is a consumptive until too late.

Why do such an insignificant number receive an opportunity to recover and why is the disease not recognized in time? There is nothing to be gained by quibbling or evading the answer. A large proportion of the medical profession does not, cannot, or will not detect the presence of pulmonary tuberculosis during the incipient stage. There can be no other explanation of certain deplorable conditions, and the best remedy lies in the honest admission. It has been claimed that many poor patients do not consult a physician at the right time, and this is sometimes true, but the comparative number is small.

With very few exceptions the unfortunate patients who failed to gain admission at Ray Brook had been under the observation of one or more physicians for months, and most of them had been treated for bronchitis, catarrh, and obstinate cold, or something else. Furthermore, the experience of physicians at health resorts frequented by the well-to-do reveals a similar tendency to delay sending patients away until evidence of advanced disease is only too plain.

An unknown percentage of unfortunates fall into the hands of physicians whose practice is more or less tainted by a growing commercial spirit. An overcrowded profession, the cost of living, a superabundant supply of alleged medical colleges, and variegated forms of healing account somewhat for the fact that the sufferer from a long-continued chronic disease is valuable prey. The consumptive has long been the dupe of the quack and the "patent medicine" harpie, effectually aided by a modern and enlightened press whose business manager is usually located nearer the earth than the editorial force.

In a search for reasons why beginning tuberculous disease escapes the notice of the physician, the most natural one seems to be that he has not been taught how to find it, and the fault is to be found in the medical school and the textbooks. Many physicians have never seen, to recognize, or examined an incipient consumptive. Their education was confined to the study of the advanced lesions and the later signs and symptoms.

Probably the greatly exaggerated importance as-

cribed to the presence of the bacillus in the sputa and the dependence on this as the only positive evidence has done more than anything else to distract attention from other reliable clinical signs of disease. As a matter of fact the appearance of the bacillus may usually be regarded as a late manifestation. There are instances when its presence may be one of the first indications of certain obscure forms of the disease, but as a rule with few exceptions definite physical signs are evident some time before it can be found. Usually bacilli are not ejected until considerable destruction of tissue has occurred, and the lesion and its nature may be very apparent long before that time. Much needless inexcusable delay may thus be caused by waiting for its detection.

Cases of closed tuberculosis will escape notice, and large affected areas may progress until an opinion is of little benefit to the patient. Quite frequently a satisfactory diagnosis can be made weeks or months before a search for the bacillus is successful. The belief that tuberculosis is present may be doubted by the laboratory savant, but the evidence is sufficient for the clinician. We often reach a conclusion with less evidence and without waiting for infallible tests. The undue significance given the bacillus has become one of the chief excuses for careless work and a disinclination to acquire clinical aptitude and proficiency. The examination for bacilli is often imperfect and haphazard and leads to a deceptive decision.

If the whole amount of expectoration for twenty-four or forty-eight hours be collected and a sediment obtained by adding a solution of phenol (carbolic acid) or liquor-potassæ and then the deposit be centrifugalized and spread on a number of slides, the bacillus will be found more quickly in the end and also more frequently. Practically all cases of pulmonary tuberculosis observed during life may progress to the state when bacilli are perceived, but the extent of the lesion and its effects may be checked by treatment in the meantime. With the admission that the bacillus should be looked for as a positive aid in diagnosis and that its presence may be quite invaluable in confusing conditions to substantiate or confirm a difficult conclusion, let us dismiss that agent and consider other methods which we are compelled to employ. Most of them were well known to some of the older authorities, but they have assumed added significance as our knowledge of proper care has advanced. Their study and application require more effort, time, and patience than the dispatch of a specimen and the receipt of a report.

When tuberculosis is suspected a careful consideration of the family and individual history becomes more and more important because the diagnosis and prognosis are becoming very closely allied. A case may be incipient and favorable or unfavorable. The importance once assigned to heredity has undergone a decided change. This is apparently somewhat due to the fact that we may call things by other names. The statement that the disease cannot be inherited or directly transmitted is not entirely true, because the bacilli have been found in the placenta and the fetus of the tuberculous mother.

Exactly how predisposition will account for the tendency of the young children of tuberculous parentage to die of tuberculous meningitis and other forms of tuberculous disease is not quite clear, and I fear the last word concerning heredity, predisposition, and latency has not been said. Something is inherited which makes it worth while to scan the family history and remember that types and tendencies should not be overlooked. The recent attempt to discover evidence of immunity conferred by tuberculous parents might be very interesting if it rested on more substantial proof.

Valuable information can often be obtained by investigating the possible or probable opportunity for infection. Has the patient been exposed by occasional or close contact with a consumptive in the same house or shop? This is particularly important when the contact has been prolonged or proper preventive measures neglected. Kaiserling and others have shown that the disease can often be found by examining members of the family thus exposed. Sometimes repeated examinations of the apparently healthy person who lives with a consumptive will reveal the evidences of disease before any symptoms appear or attract the notice of the individual. I offer an illustrative case.

Miss S. lived in close contact with, and cared for, a sister suffering from advanced consumption. To the best of my knowledge proper means for prevention were observed. Miss S. called on me several times at intervals of two weeks, requesting an examination of the chest as a safeguard. In the course of time I discovered signs of an invasion of the left apex. She was apparently in robust health and betrayed no symptoms whatever. Two and one-half weeks after the discovery of the disease a slight cough and an evening rise of temperature developed. There was a very slight loss of flesh and no expectoration. She was sent away and seven weeks later the expectoration contained bacilli. She apparently recovered and remains in good health after the expiration of two years. These cases offer the best opportunity for the study of slight lesions during the stage of invasion. Furthermore, the physician does not perform his full duty if he fails to keep exposed members of a family under careful observation. The importance of repeated examination of individuals exposed to infection has not been sufficiently emphasized.

An effort should be made to learn if the patient's history reveals evidence of a preceding attack. The lesion under observation may be secondary and due to an auto or reinfection. Antecedent attacks and the signs of an old lesion are much more common than is generally supposed. The patient may recall a period of ill health, characterized by fever, loss of flesh, etc., ascribed to a cold or influenza, or possibly the symptoms of a localized pleurisy may have been present. An examination may disclose both the old and the new focus of disease. There may be signs of a healed or quiescent lesion in one apex and active disease in the other. Again, and this happens rather frequently, a quiescent or temporarily closed area of tuberculous lung may, after an indefinite time, display acute exacerbation and be mistaken for a primary infection.

The opinion that all pleurisies are tuberculous in origin is already in process of revision, but the history of attacks not accompanied by pneumonia may be included with suspicious testimony. The presence of bacilli in the pleuritic effusion can sometimes be determined by inoscopy when other procedures fail. Even if we assume that a large percentage of cases of pleurisy with effusion are tuberculous in origin, it does not follow that tuberculosis of the lung will accompany it or even supervene.

The following definition of incipiency has been

adopted by the National Association for the Study and Prevention of Tuberculosis: "Slight initial lesion in the form of infiltration limited to the apex or a small part of one lobe. No tuberculous complications. Slight or no constitutional symptoms (particularly including gastric or intestinal disturbances or rapid loss of weight). Slight or no elevation of temperature or acceleration of pulse at any time during the twenty-four hours, especially after rest. Expectoration usually small in amount or absent. Tubercle bacilli may be present or absent."

Obviously any brief definition will be subject to criticism and cannot for many reasons be employed arbitrarily. Tuberculosis of both apices may be slightly manifest and the condition favorable, but as a rule it is followed and not accompanied by involvement of the other. The inclination to regard incipiency simply in relation to time is quite general. The duration of the disease is quite conjectural, and with few exceptions it has been present much longer than is assumed. A morbid process may also be recent and yet extensive, progressive, or very grave. A slight lesion may produce profound systemic disturbance or the individual resistance be unusually marked.

In considering symptoms it must be remembered that we are dealing with an insidious disease. From the time of infection months may elapse before objective or subjective symptoms are pronounced. Those deserving special study are in the order of their importance hemorrhage, fever, loss of weight, chlorosis or anemia, loss of appetite, and cough, with or without expectoration. All these symptoms are rarely associated in the early stage.

Hemorrhage occurring during the incipient stage or as an initial manifestation seems to be somewhat rare in the eastern States. In my experience it is recorded in about 5 per cent. of this class. At the New York State Hospital an examination of the histories of 285 cases of incipient tuberculosis shows that hemorrhage occurred in 19 per cent. When other causes have been excluded its significance cannot be too strongly emphasized, and the history of a hemorrhage antedating by months or years more recent suspicious symptoms should invite a search for a previous lesion.

A rise of temperature at some time during the twenty-four hours is probably the most frequent symptom on which we may place much reliance. This symptom is more frequently overlooked than any other. There is absolutely nothing to be gained by asking the consumptive if he has fever. The advanced case will visit the physician's office daily, if the physician is foolish enough to allow it, and insist that he has no fever when the thermometer will record a temperature characteristic of typhoid fever. A temperature of 103° or 104° F. is frequently seen. Not more than two per cent. of the early cases will have any sensation of fever. The highest elevation of temperature usually occurs between the hours of 4 P.M. and 7:30 P.M.

The morning temperature, as a rule, is normal or subnormal, even in febrile cases. Consequently little or no dependence can be placed on any observation at that time. If a case is to be closely studied the temperature should be taken every two hours from morning until evening and the rectal temperature is more reliable. There are instances when the presence of fever is entirely overlooked unless this rule is followed. Thus a marked daily rise of temperature may occur only at noon and be absent in the afternoon or evening. It is a wise precaution to examine a suspected patient in the evening. Exposure to cold air, particularly if prolonged, has an influence on the febrile curve. Allow the patient to wait until he is warm on a cold day. Otherwise the thermometer may require from four to ten minutes to register the actual temperature. Many of the new cheap thermometers require an insertion of several minutes instead of one to register properly.

Whether the temperature is taken after exercise or rest will be more noticeable in a consumptive than other patients. Fever is usually more marked in children than in adults suffering from tuberculosis, and it is often temporarily increased during menstruation and an attack of indigestion. A diurnal rise of temperature due to syphilis, intestinal toxemia, or neurasthenia is apt to be most puzzling and sometimes difficult to exclude. To assume that an active lesion is always associated with fever may be misleading at times, but it is often an excellent guide.

Loss of weight is usually slight and gradual, not rapid and great. The standard of weight for the individual should not be fixed at the highest ever attained. Age, habits, and the mode of living should receive attention, and the statements of patients concerning their normal weight is often most unreliable. In view of the chances for error, it seems safe to compare the present with the average weight while in health. There is usually a difference of two or more pounds between the morning and evening weight. The loss of appetite and indigestion are of decidedly relative value, because they are so common in other conditions. Chlorosis and anemia are much overestimated as early symptoms. They are frequently due to other causes and more frequently follow extensive disease than precede the state of invasion. The fact that chlorosis and neurasthenia have an influence on the prognosis is another matter. A decided leucocytosis, however, may be of signal assistance at times in eliminating tuberculosis and directing attention to other forms of infection.

Practically all textbooks lay stress on cough as an early and most constant symptom. Very often it is due to pharyngeal irritation and subsides after local treatment. Many times the so-called hacking cough owes its origin to nervous habit and disappears by an effort of will or as a result of suggestion. It is not nearly so common among men as it is among women. As an early sign of tuberculosis its importance and the frequency of its presence have been much exaggerated, but it performs valuable service by directing attention to the chest. Physicians who visit a sanatorium for the care of incipient consumptives are always surprised by the absence of coughing.

All the symptoms which lead to a suspicion of pulmonary tuberculosis should be considered, so far as possible, in a group, and their chief importance will be found in encouraging thorough and repeated examinations of the chest. We have learned that symptoms formerly ascribed to a pretubercular state are usually caused by post-tubercular conditions. It must be borne in mind that early manifestations, with the exception of hemorrhage, are due to toxemia, and individual resistance will influence the time of their appearance and their character. The earlier the diagnosis the less pronounced will be the symptoms as a rule.

In discussing the physical signs commonly as-

sociated with incipient disease, a few words may well be devoted to the reasons why they are sometimes undetected. Not enough time is spent by the student or physician in the study of normal sounds. The cardinal rule, "compare, always compare," is not always observed. The normal relative difference between the right and left upper lobes is not appreciated. The chest is not thoroughly bared, particularly in women, and the search is not thorough. The ear may not be trained or the hearing acute, and the unmusical ear may be incapable of detecting slight changes or alterations in pitch. The technic of percussion is not an easy art to learn and is only acquired by practice. The finger is not properly applied to the chest wall or the improper stroke elicits only the bony resonance of the physician's finger. The selection of a stethoscope, the fit of the ear-pieces, and the unnecessary length of rubber tubing should be considered. Opportunity for frequent practice gives one an enormous advantage, but even the skilled examiner realizes that absolute concentration of attention and plenty of time are required for careful search. While the immediate application of the ear may be preferred, the spaces above the clavicles cannot be effectively examined by that method.

Experience has shown that any type of chest may be invaded by the bacillus. When invasion is localized and the focus slight in extent, the chest will, as a rule, reveal no significant change in conformation. Depressions in the chest wall and relative lack of movement in certain localities are much more noticeable when the disease has advanced to a more marked degree.

By aptitude and much practice the sense of feeling may become very acute, and some observers rely much on evidence obtained by palpation. The signs elicited by palpation are necessarily of a collateral value. The excursion or modified function of a small portion of the lung can be studied more accurately by other methods, and the transmission of fremitus as revealed by sense of touch at the apex may be very deceptive. Many teachers and textbooks apparently assume that the chest is to be examined while the patient breathes in the natural or accustomed manner.

After an individual has relinquished active exercise the full, deep breath may be a rare event or an exertion. This is particularly true of women. Furthermore, deep expiration very frequently must be taught. Probably one of the principal reasons why the early signs of pulmonary tuberculosis escape attention is the fact that full exercise of the lungs is not enforced to gain information not revealed otherwise. It is quite frequently impossible to find distinctive signs without obliging the patient to breathe in and out forcibly. The movement of the tip of the lung, the extent of impairment or consolidation, the character of the expiratory murmur, and the presence and nature of râles can very often only be determined by this method. A proper examination should include observation during natural and forced respiration. The commonest location of beginning disease is at the apex, and the initial focus is apt to be found about one and one-half or two inches from the tip of the lung posteriorly. An analysis of the histories of 285 incipient cases admitted to the New York State Hospital shows that the lesion was located as follows:

Right	Upper lobe,	171	60.5 per cent.
	Lower lobe,	14	4.9 per cent.
Left	Upper lobe,	98	34.3 per cent.
	Lower lobe,	2	.7 per cent.

Thus in 95 per cent. of cases the lesion was confined to the apex.

When tuberculosis of the lung accompanies or follows pneumonia or pleurisy it is more apt to develop in the middle or lower lobes, but our attention to-day is confined to the insidious incipient variety. Percussion and auscultation should include the apex of the lung which extends during inspiration one to two and one-half inches above the clavicle. The note on percussion will show relative dullness compared with the other apex or another portion of the lung. Strong and light percussion may both be necessary to bring out the sound, and the note can be analyzed or defined as shorter in duration, higher pitched, and quality modified.

Sometimes if the change of pitch cannot be appreciated it is of assistance in comparing to hum and endeavor to imitate the gradation of change. At times a sense of resistance to the finger can be felt. Delimit by percussion the movement of the tip of the apex in the region of the neck and mark with a pencil the height to which it rises on full inspiration. The diseased lung may be restricted by infiltration, consolidation, or adhesions, and the extent of its movement modified proportionately. Of course, one must remember that the right apex is normally relatively dull and higher pitched than the left. A lesion at the right apex is for this reason more difficult to recognize, but the danger of error has been decidedly overestimated by some authorities on physical diagnosis. The note on percussion can be compared with adjacent areas, and by repeated examinations the extension of the dull area can be watched. Again, the play of the apex can be quite accurately determined by Kornigs' method.

The change in the respiratory murmur most frequently revealed by auscultation may be characterized as modifications of bronchovesicular breathing. They are distinguished by slight increase of tubular character, and the expiratory sound which is the essential element to study is relatively higher pitched and prolonged. Decided confirmatory evidence will be found if fine râles can be detected. They must be distinguished from the coarse, distinctly moist râles in the larger tubes. The older English clinicians distinguished between them by the term clicks and râles, and the words are as truly descriptive to-day. The clicks, crepitation, or fine râles are often unobserved for several reasons. They may be very few in number, fugitive, or occur in showers. They may often be heard in the morning before expectoration has cleared the locality of secretion which accumulated during the night. The essential test is to oblige the patient to cough and breathe deeply. Many times they only appear after several efforts in coughing have pulled apart the mucous-coated, agglutinated structures.

Physicians occasionally disagree because one will hear râles and the other will not. The time of day, the temporary condition of the lesion, and the method employed may account for the difference in observation. In some instances the only sounds discovered by auscultation are diminished breath sounds. In such cases signs of activity may be heard over adjacent territory, and particularly near the clavicle. If only suppressed breathing is heard, other signs must be considered to obtain evidences of a deposit, which is almost sure to be tuberculous at the apex if there is no evidence of other thoracic disease. Cogwheel respiration may lead to suspicion, but it is not of distinct diagnostic value. It

can be heard in many nervous patients and may be found on one examination and absent at another. A distinct friction sound, which can surely be designated as such, is rarely heard, except when the lesion is old, and it is much more indicative of a secondary pleurisy when its appearance is temporary.

Finally the transmitted whisper is of decided value in confirming the presence of morbid changes over a small area. Many times the increased audibility and high pitch of the sound will denote infiltration or solidification and remove doubt caused by indefiniteness of other signs. The transmitted whisper affords a much more delicate and reliable test than the speaking voice, particularly if the latter is high pitched, weak, and not penetrating. I have deliberately avoided mentioning roughened breathing during inspiration as a reliable sign. If the word harsh, as employed by the Germans, has been confused, that is another matter, because harsh breathing may be simply a modification of bronchovesicular breathing which becomes more marked later. The differentiation between a recent slight lesion caused by tuberculosis or syphilis or one following influenza is seldom called for, but it can usually be accomplished if the history and all the clinical evidence is closely scrutinized.

The tuberculin test as a positive indication of tuberculosis offers opportunity for difference in opinion and discussion. The tuberculin is injected into the patient, not into the physician. This may explain somewhat its frequent employment when quite unnecessary. The unprejudiced observer who has watched the pendulum swing can still afford to be conservatively skeptical concerning some positive tests. The character of the product, the dose, and the technique certainly require more consideration than has generally been given them. My personal experience has been very slight, because instances when its use might seem necessary or justifiable have been extremely rare. Opportunity to observe its employment by others when it seemed unwarranted and savored of needless interference have been more common.

After the other evidence of pulmonary tuberculosis has been carefully collected and sifted, if doubt still exists, continued watchfulness will practically always remove uncertainty in a short time without detriment to the patient. The most proficient examiners use the test the least or not at all. A reaction may not furnish the knowledge which the clinician desires. If we are willing to assume that the reaction is infallible we must still decide, if possible, where the implantation exists and what is its character.

Allow me to cite two characteristic instances to exhibit the possibility of error if a diagnosis is based upon this test. An opinion was ventured that one man was suffering from aneurysm of the arch of the aorta and another of sarcoma of the mediastinum. Other physicians disagreed and ascribed the manifestations to tuberculosis of the lung. Both patients were given tuberculin and decided reactions followed. A positive diagnosis of tuberculosis of the lung was then made. Both of the patients died within a few months and an autopsy revealed no evidence in either case of any disease in the lungs. The original diagnosis was confirmed. Whether tuberculosis existed elsewhere in these patients I do not know. The uncompromising advocate of the tuberculin test always has the advantage because no tangible evidence is required. These remarks would seem to apply to the test by Calmette's or Pirquet's method.

But the contribution made by Franz is most interesting and suggestive. He tested with tuberculin the members of two Austrian regiments. They were supposed to be in good health. Sixty-one per cent. of those in the first year of service reacted to doses of 1 to 3 mg. and 69 per cent. in the second year of service reacted to similar doses, but not content with these results Franz asserts the belief that the injection of 10 mg. would have shown 100 per cent. of reactions. The purpose of this investigation by Franz was to learn the number free from tuberculosis. Evidently the clinician will have to be content with the recognition of tuberculosis when he can perceive evidence of its location, extent, and character. When the tuberculin test seems to be demanded what conditions which may give a similar reaction shall we exclude? Will the influence of suggestion and the presence of syphilis or chlorosis complete the list or are there other causes still unknown which may mislead?

When the consideration of treatment is limited to the incipient case there is slight room for any controversy. The earliest possible diagnosis should be followed by the immediate employment of the only method or procedure which promises anything. The prime requisites are rest for an indefinite time, pure open air, and a full diet. The patient should be under the care and control of a competent physician, and discipline is an essential attribute of the plan. There are many details in management which influence the result, but time will not allow of their discussion. One very essential part of the treatment is too often disregarded. I refer to the mental condition of the patient.

The patient who can gain admission to a properly conducted sanatorium has a decidedly better chance for recovery than another who is not under close observation. A rigid routine and close supervision of the character and quantity of food are large factors in the result. Most patients reach recovery by the aid of the alimentary tract. A change of climate undoubtedly contributes much toward recovery, especially if it is more favorable for treatment or allows more comfort. The advocate of home treatment does not usually spend his vacation in his back yard.

Certain localities have gained a reputation for supplying conditions exceptionally favorable. Purity of the air and freedom from dust are two of the essentials. The climate of Colorado and some regions of New Mexico and Arizona offer advantages not to be found in the East. Dryness and equability and a much larger amount of sunshine constitute the chief attributes of superiority. The ability to seek a favorable climate and environment is limited to the few, but fortunately experience has demonstrated that the incipient will recover in a large percentage of cases by proper care in his own State or county. In this State there are numerous localities, some known and many untried, where excellent results can be obtained.

The immediate imperative demand is for more extensive care of the poor consumptive. There is little encouragement now to provide greater opportunity for common-sense treatment if the disease is not recognized until too late to secure easily obtainable results. At the present time there are more institutions for the care of incipient cases than seem to be needed. If the demand for enlightened care and greater accommodation for the earlier cases were made by the physician and the sufferer, comprehensive plans for relief could be devised and executed. This State (New York) has inaugurated the movement and the experiment has proved to

be a complete success. More sanatoria designed for curable cases should be erected in this State, and we should count the inmates by thousands instead of hundreds. The buildings and the equipment can be and should be made inexpensive. The model sanitarium for the poor in the future will be the one which costs the least and accommodates the greatest number. The money will be spent for food and not for luxurious buildings and rooms. Every dollar wasted helps to deprive some unfortunate of a chance for his life.

A physician qualified to conduct a sanitarium according to modern methods can obtain better results if you give him a barn with enough openings and a kitchen than some of the county and city hospitals where the old routine is followed. Young men trained in the diagnosis of tuberculosis and the methods of sanatorium care are greatly needed in this country. The development of State care alone will necessitate this new class equipped with expert knowledge. Good results are obtained in apparently unfavorable climates if simple rules of management and the introduction of essential requirements are combined. The place to study methods of control and treatment is at a hospital for incipient consumptives, not a home or boarding house falsely called a hospital, where advanced cases wait for death. There are great advantages to be derived by sending the poor consumptive of the curable class some distance from home to an institution favorably located within relation to helpful influences. Visiting and distraction are obviated, more strict control is possible, and the patient realizes that he must devote months to one object.

I have on several occasions presented arguments to show that the care of the early case should be intrinsically a State problem, and time and experience strengthen the hope and conviction that the State will ultimately be gradually forced to assume the charge. Our battle for improved care of the consumptive is not won, because we lack harmony in ideas and unity of purpose. One urges home treatment, another would devote all care to advanced cases, many would confine all action to prevention, and some in the rear ranks want to try one more alleged remedy or are waiting for the discovery of a specific curative agent.

At present the revival of tuberculin treatment in the form of small doses administered through a long period seems to be gathering force for a wild sweep over the land. At times the history of medicine seems to have been written in vain, and all the grim wrecks strewn along the crooked path of progress are totally disregarded. The widespread, general, and indiscriminate use of tuberculin will cause infinite harm. The fact that the dose advised is so small that no direct ill-effects will follow is not the question involved. A danger lies in reliance on a form of treatment which, if used alone, will prove disappointing. Patients unwisely selected for this treatment are being kept at home, while months are consumed in the trial of a new method, and the fact is unheeded that those who have had sufficient experience to form any judgment of its value have employed the remedy in carefully selected patients, who also enjoy the beneficent hygienic conditions which are known to be the most successful.

The results, when any are claimed, are rather indefinite and to a certain extent assumed. Tuberculosis is preeminently a disease of exacerbations and lulls, and this fact coupled with the mental effect produced by any new treatment accounts largely for remarkable results observed by enthusiasts. It would be difficult to devise a method of treatment more financially remunerative to the unscrupulous and selfish physician. An excuse can be offered for keeping the patient at home indefinitely and the necessity for making a prompt diagnosis and sending the patient elsewhere is avoided.

The great white scourge must be attacked by manifold measures, and the problem is colossal. Science must be blended with pity, charity, and remorse. The results of stupidity, apathy, and neglect must be met and remedied. The dangerous consumptive is the neglected consumptive. The unafflicted must be protected from the living dangerous victim, who typifies the accusing appalling proof of inaction, and the hopeless wreck should have his tottering, weary journey to the grave made as easy and gentle as the "ebbing flow of life" will permit. The hope of redemption and the result of the chief struggle in the conflict will depend principally upon one fixed resolve.

Find the consumptive at the right time and help him in the right way until he is well. If you ignore or neglect him too long pay the full penalty by protecting the public and helping the poor victim until he is dead.

Buildings for the care of the incipient consumptive have been and will be erected in many States. The medical profession must learn to recognize the victims of the disease before these institutions can fulfill their purpose.

At one time most of the consumptives died because they were poor. Now most of them die because of ignorance and apathy. The medical profession needs education as much as the public. "Volleys of eternal babble" will not conquer consumption. There has been plenty of talk—what we want now is action aroused by a saving sense of duty and governed by common sense.

SOME POINTS IN MEDICAL EDUCATION CONSIDERED FROM THE STANDPOINT OF THE STUDENT.

By BENJ MICHAILOVSKY, B.S.,

NEW YORK.

Of late years the members of the medical profession of this country as well as of Europe have begun to feel more keenly the essential similarity of their interests and the advantage of protecting these by concerted and cooperative action. The endeavors to obtain an exact definition of the term "practice of medicine" by the legislative bodies, the defence of the public against quacks and charlatans, the cooperative efforts in protecting physicians from blackmailers, all serve as examples of the new spirit of solidarity in the profession. More important for the progress of medicine in this country, however, has been the growing inclination of the great professional body to take interest in and to supervise the educational institutions that give or claim to give a training in medicine. This spirit has already led to much improvement in obtaining equivalent requirements for admission to the various colleges and in weeding out some few institutions that have carried on their work without proper facilities for instruction—being mere diploma mills to a greater or lesser degree in each individual case. At the same time the methods of instruction in the legitimate institutions have undergone much radical change tending toward a more rational and effective training of the students: didactic lectures have large-

ly given place to recitations, objective and clinical teaching has been enlarged in scope, and better facilities have been introduced for the scientific observation of the phenomena of disease and their study by the newer laboratory methods. This is not the place to recount the great progress obtained by the means outlined above; everyone conversant with the subject has seen the growing success of the American profession in the science of medicine and the increased efficiency of the average college graduate of to-day.

The whole educational system is, however, still in the making, and frank consideration of the methods now in vogue is certainly in order, so that individuals may take stock of the progress made. This article accordingly will be an attempt to consider from the standpoint of the student, however incompletely, some points in the preparation of the student for the medical course, in the recitation versus the lecture system of instruction, and in the qualifications of the teachers of medicine, the material having been gathered by observation of the teaching methods in Europe and America and some experience in the application of them.

Perhaps the most surprising phenomenon presented by an average medical class, consisting for the most part of college graduates or men with an equivalent amount of preliminary training, is the almost total inability of the students to make use of modern languages to the study of which they had previously given from two to five years of their time. It is startling to learn that hardly a student in a class can look up a reference in the German or the French language, or ask of some foreign patient the few words about the symptoms of his disease or the seat of his pain. Often enough one hears that the language ability is a matter of race and nation; this is perhaps true so far as real knowledge of a foreign language is concerned, but it has been the experience of the writer that such national limitations apply but little to the elementary knowledge of languages, and especially to the reading knowledge of them. Moreover, no body of cultured men ought to be satisfied with such a *testimonium paupertalis* as an explanation of their ill-success in one branch of human knowledge. If a few students only were to show this deficiency the explanation might have been individual; because the great majority show it, the explanation is to be sought not in the conscience-easing national disability, but in the one factor more nearly affecting all the students in a similar fashion, in the methods, namely, that are used in teaching foreign languages. Too often the latter are made mere excuses for training in the rules of formal grammar the reverence for which has come down to us from the casuistical days of old, or mere dry-as-dust work with dictionaries and texts is continued to the degree of producing hate for all language study. The real "fruit-bearing stage" is never reached, the love, that is, for the beauties of a foreign literature or the familiarity with the every-day talk of the people. This is not the place to discuss the methods of teaching languages, but certainly the senior college student, who has decided to take up medicine on graduation, ought to be given special opportunity to acquire the reading knowledge of one foreign language at least, namely, German, that forms such an asset in the intellectual, if not commercial, success of a physician.

Another matter often noticed by the instructors of medicine is the weak impression that the academic courses in natural philosophy have apparently left upon the minds of the students in so far as the formation of a scientific attitude of mind is concerned. Many a student well remembers the formal data of science or can reproduce in his mind the vivid picture of some sensational demonstration he had witnessed, the conversion of a diamond into ash, let us say, the oxyhydrogen blow flame consuming a steel sword, or the mass of mercury frozen into a solid cross by the action of liquid carbonic acid gas and triumphantly lifted aloft by the professor of chemistry; yet he is unable to recognize the chemical and physical principles when confronted with them hidden in the structure and functions of a living organism. The phenomena he has watched *in vitro* appear unfamiliar when made manifest *in vivo*, because he has not been taught to realize the application of the principles evolved from the study of formal science, nor helped to bridge over the gap between the laboratory on the one hand and the healthy or the diseased organism on the other. This gap becomes yet more apparent at another period of the medical course, in the transition from the fundamental studies, like anatomy, physiology, and pharmacology of the first two years to the subjects more directly concerned with the human body in disease. Parallel with this may be observed the poor training that the students have had in working things out for themselves, in looking up a subject even in their native tongue, in using indexes, tables of contents, reference books, in availing themselves, in a word, of all the tools of a worker in practical or scientific medicine. It is quite instructive, in this connection, to watch the undergraduate medical student in the libraries connected with the college or in such institutions as the library of the New York Academy of Medicine; usually he may be observed wandering about for a few moments, only to settle down at last with the identical text-book before him, prescribed for him in the college. Lucky he is if that book represent the work of a teacher and an authority in medicine, for often enough it is only a compend of the subject. Nor is such helplessness indicative of lack of interest, for no young man is more enthusiastic than the young student of medicine; the whole trouble lies in inefficient training in just such independent work while in an academic institution.

Turning now to the education in the medical college proper, it will perhaps pay to state at once what in the writer's opinion is the weakest point of the whole system. This is the widespread ignorance of the laws and principles of pedagogics on the part of those whose occupation to a certain degree consists in the exercise of that art. Men usually become teachers of medicine after a hospital course and some years of practice, and their knowledge of the subject matter need not be questioned. But the knowledge of the subject matter is but one-half in the teaching of a subject; if it is not combined with the ability, whether natural or acquired, to impart it to students, it is so much dead ballast as far as its educational possibilities are concerned. It may be of the greatest benefit to the doctor or to his patients, but it will not teach medicine to students. Medical knowledge is written large in many dead books, medical teaching power lies in the brains of living men. Nor is such power anything hard or impossible to attain. There are some that are born teachers and their path is easy; there are some that never can become teachers and their path may be easy too, if they only keep out of the teaching profession; the great majority, however, are men that can learn the science and art of

teaching just as they have learned the science and art of medicine, only they must take the time and have the desire to do so. A teacher of physiology or of biology in a high school, for instance, is required to know his subject and then give fair proof of having studied the art of teaching; a teacher of the same subjects in a medical college, where they are incomparably more important, need only have the knowledge, the teaching power is supposed to go with that.

Let us consider the results that follow such a condition of affairs. The lecture system has been abolished in many departments, because it is too didactic a method and gives least opportunity for individual instruction. How often, however, the only change produced has been that lectures are now delivered to an audience of twenty to thirty students gathered in a "recitation room" instead of to two hundred men gathered in a "lecture hall." In such cases the old lecture system had the advantage of economy in men, time, and space. Such result, of course, is due to the one thing mentioned above, the lack of training, that is, in the art of education on the part of the instructors. In this "recitation room" an earnest worker, who has never, however, considered educational methods, literally dictates the subject matter to his students, using only the last few minutes for the discussion of the subject and the asking of questions. How much better were it to provide the students with a fairly complete *résumé* of the subject, have them read up the matter in the books of reference, thus forming an "apperceptive mechanism" in their minds for the reception of new knowledge, and then deepen and illuminate the facts they have obtained by judicious and logical questioning. Another instructor calls out some favorite name in the class, approaches the owner of it as near as possible, asks him some question, and then spends ten to twenty minutes in discussing it with him. These few minutes may be very profitable to one or two students called up each recitation period, but the rest of the class is meanwhile conscious only of the uncomfortable seats or the bad light, or have fallen into that state of mental vacuity that so often is but the reflection of inefficient teaching in the minds of the students. Yet the pedagogical principles involved are perfectly plain and simple. Let the question be asked first, before any name is called, so that in every mind the almost reflex attempt at formulating an answer may begin. Then call upon some one for the answer, quickly drawing other students into active thinking participation in what now may become a recitation indeed. It is, of course, obvious that every successful teacher must develop the ability to carry on so-called "socratic questioning," the faculty, that is, to frame questions so as to wake up the greatest possible number of associated ideas in the mind of the students, helping them on with the logical answer without giving it away, as is so often done. This requires the power of using the native tongue well—certainly a little thing to ask of a teacher.

Certain conditions surrounding instruction in the higher institutions serve to keep the instructors quite ignorant of the degree of success that attends their teaching efforts as well as of the pedagogical correctness or non-correctness of them. Anyone who has ever spent a few days in an elementary or a high school knows that no instruction is possible there without the maintenance of discipline in the class; everyone knows at the same time that such discipline, in the long run, can be obtained only by correct educational methods that attract the involuntary attention of the children, stimulate their interest in the work, and keep them thus out of mischief. Quite a different state of affairs reigns in the domain of an instructor in a medical college; no "spit-balls" fly about, if his teaching does not attract the attention of the class; no blank caps are exploded, no cat-calls are heard, if he chances to turn his back. A man may thus plod along for years and years in blissful ignorance of his ineffectual work as a teacher, being only occasionally startled in his peaceful career by the number of failures in the year-end examinations. Much is said nowadays against the private "quizzes" that exist about the medical colleges, and it is perhaps true that they tend to separate the student into two camps, and are apt to give too much respect for the "practical knowledge" of medicine and for hospital examinations. Yet quizzes exist largely because instruction in the colleges is not good enough: as they are commercial enterprises, little sentiment is attached to the selection of the quiz-masters, and the men doing the work are among the best teachers of medicine. The same "natural selection" could be well imitated in the college by allowing the students of the last two years to select their own instructors somewhat in the manner of the "privatdozent" system in Germany, whenever parallel courses in the same subject exist for the various sections of the class. Such power of choice may be safely intrusted to the students of the third and the fourth years, if the college authorities extend their endeavors to raise the average mental caliber and preparation of the students more often beyond the admission requirements. At present, after the ordeal of admission is safely passed, the gates of the college are somewhat too widely open for the entire four years to such as are willing to study medicine; perhaps a little more rigorous selection of those that are not only *willing* but *fit* to study medicine at the end of their first or second years might keep the average higher and prevent such a drag upon a class as great differences between its individual sections. No tears need be shed over those that may be compelled to leave the better colleges at the end of their first or second year; just as there are private tutors and special preparatory schools a-plenty for the unsuccessful in the regular institutions, so there will always exist medical colleges satisfied with a lower average of their students, if only their tuition fees be paid regularly, and their ability be not below the "quiz-compends" used in preparing for the State license examinations.

Thus it becomes evident that the knowledge of the pedagogical principles, as they are taught in our normal colleges, and daily used in the schools of the land, are just as important to the teacher of medicine as to the teacher of arithmetic or geography. However different the subject matter, the content of knowledge, the attitude and the processes of the human mind are very much the same, and may be reduced to the two fundamental principles of induction and deduction. Let but the insight into these processes, as they go on in the minds of the students, be acquired by the instructor, the teaching ability will not fail to follow, while the question of method will become easy indeed. There are many workers whose efforts have introduced new and efficient procedures into all branches of teaching. In medicine one might cite the case method: the students are given good histories of real cases of disease and attempt to gather from these the

pathological conditions responsible for the phenomena, until a working diagnosis is arrived at. Using now a more or less deductive method, the students discuss the symptoms that should have been present, if this diagnosis is correct, and compare these with the history. If the case has been followed by an autopsy, the objective findings serve further to justify or break down the diagnosis made. This method, first used by Dr. Cabot in Boston, has been adopted by other workers, and should certainly be tried in connection with the more descriptive and orderly book work. Just the same warning may, however, be repeated: the mere adoption of the method may not be expected to lead to the results desired; behind it must stand the skillful and well-trained teacher, for the sharper and more efficient the tool, the more skillful must be the user thereof.

A few words will suffice as far as lectures are concerned. There certainly ought to be no longer any room for the old didactic type of lecture, written for a former generation, and repeated year in, year out, sentence for sentence, joke for joke, to those that have no access to the usual well-worn copy of them that goes the rounds of each successive class. Such lectures not only waste the time of the students, but give rise, in addition, to a false feeling of security in the subject treated; there is little temptation to go beyond them to books, it being usually assumed that they are sufficient to pass the requirements of the examinations. There is ample room, on the other hand, for another type of lectures that require no note taking, but gain the undivided attention of the hearers by the mere interest of them. I refer to general lectures introducing the science of medicine and its main divisions, or treating of modern ideas and modern progress in that art and science. Presented in a perfunctory way, such lectures are, of course, worse than useless; they require, indeed, mastery of subject and language, but in such a case their value in engendering and stimulating the interest of the students can hardly be overestimated.

When we turn to the later years of the student in a medical college, we meet with about the same picture in a somewhat different setting: the application or the neglect of the principles outlined leads in the one case to a great success in the teaching value of a clinic, in the other makes it a useless procession of patients that accident has brought together in that room at that time. One demonstrator gives the diagnoses away even before the patients are brought in, proceeding to name the symptoms without illustrating them on the real case present; the students, no longer interested since the keyword has been given, passively listen to the demonstrator and promise to look up the matter in their books. Another man, this time a teacher, selects the cases so as to illustrate a few conditions only, shows, perhaps, other cases at the same time, similar in many respects, yet manifesting some differences that throw the others into a striking contrast, has all his hearers on the *qui vive* for the understanding of the phenomena presented, and thus teaches the most difficult and the most important art in medicine, the art of diagnosis. To conduct a clinic thus will require, of course, an extra amount of preparation, a careful selection of material, and in some cases the moral courage to transfer the duty of demonstrating to some younger man, who may have better insight into the difficulties of the students, though his name in the medical directories be followed by little more than the place and the date of his graduation.

Another matter concerns the position of the hospital in medical teaching. No one will deny that at present a great deal of valuable material is not utilized for scientific investigation or for teaching purposes merely from the lack of men to do a certain amount of routine work. Yet what has become mere routine work to a laboratory man or to the "house physician" is new and full of interest to a third or a fourth year man. Moreover, the students ought to do some of the work now left entirely to the nurses, such as the taking of temperatures, the counting of pulses, the tubbing of typhoid cases, perhaps, and the like. The maternity hospitals provide accommodations for the students during the eminently practical course they give, and it would seem feasible for the general hospitals to do the same, so that a few men at a time could be made responsible for the welfare and general management of some specially selected cases in the wards. At present many of the things mentioned are left to be learned during the hospital internship, where the time could be used for better purposes; many students, too, are unable to take the hospital training and would be greatly benefited even by a short stay in the hospitals during their student days.

One more subject remains to be considered, and that is correlation of studies. It may be granted that four years is a short period of time for a modern medical course, but a great economy of time and effort could be obtained by presenting the several branches of study in their proper relations to each other both in time and the manner of teaching. Often enough, to give specific instances, the therapeutics of some diseases are taught before the clinical picture is presented, an outdoor obstetrical course is given before the student has had the opportunity to witness model deliveries in a hospital, or, what is perhaps more important, a class studies "inflammation," let us say, talking glibly of leucocytes, giant cells, etc., knowing these elements by little more than the mere sounds of their names. Of course proper correlation of studies and the use of more objective methods of instruction would do away with such anomalies. Again, the growth of the various branches of medical science, both pure and applied, with the inevitable specialization demanded by it, has in many instances given rise to a curiously narrow disinclination on the part of some instructors to consider any phenomena not directly bearing upon the subject of their department. But the pure scientist or the specialist engaged in the teaching of medicine must never lose sight of the fact that his subject is presented as a part of a general medical course and must be connected in every possible fashion with the other studies, so that a student may obtain as well balanced a course of study as is possible in the present state of our knowledge. The inculcation of love for the pure science of medicine requires enthusiasm on the part of the instructor and special aptitude on the part of the students, while mere narrowness in presenting a subject may only strengthen the deplorable tendency seen in many students to give from the very beginning special attention to some one branch of study to the virtual exclusion of the rest; this tendency may later be responsible for the half-baked specialists or the ill-considered attempts at "research" so frequently met with nowadays. Any legitimate interests of individual students in some special branch of medical work should

be met by providing advanced optional courses in the various departments for the student of the last college year, the time for which could be easily found, if the constant waste due to lack of correlation and to inefficient teaching be done away with. The various scientific, clinical, and pathological laboratories ought to provide opportunities for a few men, who have shown special fitness, to acquaint themselves in a general way with the principles and practice of modern scientific work; nothing could be as effective in bringing out any latent interests or abilities of the students, thus helping to provide future workers in special medical branches and saving many a man the bitter experience of work in an uncongenial field at a time when change may become difficult or impossible. To forestall as much as possible ill-considered selection of special work, an advisory committee of instructors should be formed that would provide every student with the opportunity of obtaining the counsel of men of riper age and experience in regard to his career in the college or on graduation. Such opportunity exists in the private quizzes, and the above provision with the increased efficiency of recitations would serve to incorporate into the regular course the good elements of the quizzes and thus go far in obviating the reasons for their existence.

To recapitulate: the present improved methods of medical teaching fall very far short of the possible achievements that might be obtained for two great reasons. In the first place, the student body is but indifferently prepared for the reception and use of new knowledge; the remedy, of course, lies in more purposeful teaching in the academic courses. In the second place, those who are to make use of the means and methods of instruction are not sufficiently conversant with the general fundamental principles of pedagogics; the remedy for this lies in individual recognition of the fact and attempts to correct it, or in the establishment of special educational courses in the universities, of which the medical college may be a part, and elsewhere. In addition, the general arrangement of the medical course ought to be so modified as to allow the greatest possible opportunities for correlating and harmonizing the various branches of instruction, thus assisting in the final end and aim of the work, the adequate preparation of young men in the art and science of medicine.

146 West One Hundred and Twenty-first Street

THE TERM "STAUUNGS-HYPERAEMIE."

By ALFRED REGINALD ALLEN, M.D.,

PHILADELPHIA, PA.

INSTRUCTOR IN NEUROLOGY AND IN NEUROPATHOLOGY IN THE UNIVERSITY OF PENNSYLVANIA

Since the advent of Bier's treatment by hyperemia, the English speaking scientific world has been casting about in search of a concise descriptive term in its own tongue, with but questionable success.

We find a number of adjectives used to qualify this hyperemia, such as obstructive, artificial, passive, congestive, and venous, as also the noun, stasis-hyperemia. These terms are all open to the same criticism in that they fail to give a mental picture of the mechanics of Stauungs-Hyperaemie; stasis-hyperemia besides conveys a scientifically wrong impression.

To the philologist there is nothing more apparent than the fact that where one language possesses a single word descriptive of a condition or thing, another language, in order fully to convey the same idea, may have to use a phrase or a whole sentence. The Germans at times apparently avoid this by forming a colossal word by the agglutination of several components.

Now the condition present in the partial obstruction of venous outflow with a retained arterial ingress, the amount of blood thereby being increased in the part, but the circulation thereof never ceasing, is perfectly expressed by the German term *Stauungs-Hyperaemie*, and but inadequately or falsely expressed by the use of any two-word combination in the English language that we have seen so far in literature.

I think for this reason it were well to take over bodily this term into our language rather than use any of the English terms which but ill portray what we desire to express.

Use of a Ventral Bandage During Labor.—Vallee ascribes great assistance in the progress of labor to the use of a firm, wide bandage placed about the abdomen early in labor, combined with the use of the horizontal position in bed from the first true labor pains. The author discovered the value of this method accidentally, but has made use of it with excellent results since then. It is found to expedite labor markedly. The uterus is so placed that the head is applied with the bag of waters in the center of the pelvis. Pains become regular and powerful coming with increased rapidity, and labor is complete in a few hours. The bandage is so placed as to exercise a constant pressure on the uterus, and it forms a point of support for the contractions. No bad effects are found in the infant from the pressure exercised by the bandage. As the last stage begins and the pressure of the bandage is too high up, it should be assisted by pressure from the hands of an assistant, which follow down the body of the child. The pain of the contractions is much lessened by these maneuvers, and the patient is much less fatigued than usual. The bag of waters is kept intact until the last moment, and it is due to its presence and normal dilating action that labor is hastened. The placenta is much flattened and is delivered rapidly, without much hemorrhage. The method has been used with success in all presentations of the fetus.—*Journal des Sciences Médicales de Lille.*

Continuous Generalized Spasms and Acute Encephalitis of Infants.—Orazio D'Allocco describes acute encephalitis in infants as a malady that is generally met with in the chronic stage of paralysis owing to the quickness with which the acute symptoms pass and the obscurity of the symptoms. The disease comes on as a general infection, with fever and symptoms of brain irritation. A continuous, uniform, rhythmical clonic spasm comes on. The limbs are flexed and head extended. This condition is soon followed by paralysis without spastic condition. Electric excitability is increased, and there are no trophic disturbances. There is a stimulation of the central convolutions and central lobules of the one or both hemispheres. As long as the stimulation goes on the spasm continues, but when it is over paralysis supervenes. The condition may be of traumatic origin, or a true infective malady. The single autopsy obtained by the author showed that there was an occlusion of the blood vessels, for the most part venous, sometimes produced by true embolism and followed by acute inflammation or degeneration. The condition is analogous to anterior poliomyelitis. Most of the cases observed by the author were in rachitic babies and in the winter and spring. In the child, the babe, and the fetus, the causes of encephalitis, are not the same as in the adult. The venous system is more developed than the arterial; thrombosis of trunks and secondary branches is frequent and does not destroy life.—*La Riforma Medica.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, January 4, 1908.

THE MEDICAL OFFICER IN THE NAVY.

THE Government Printing Office has recently issued a pamphlet containing the reports of the sub-boards, composed of officers of the Medical Corps, the Pay Corps, and the Engineer Corps, which the Navy Personnel Board ignored in the report which it made to the Secretary of the Navy. The recommendation of the medical sub-board, composed of Surgeon-General Rixey, Medical Director G. E. H. Harmon, and Surgeon J. F. Leys was that the Surgeon-General and three of the present Medical Directors have the rank and title of Rear Admiral, the remaining twenty Medical Directors to be Captains, the twenty-five Medical Inspectors to be Commanders, one hundred surgeons to be Lieutenant-Commanders, and 197 Passed Assistant and Assistant Surgeons to have the rank and title of Lieutenant and Lieutenant Junior grade, respectively. In making these recommendations the members of the sub-board argue that the withholding of military titles confers an equivocal rank on a medical officer "which places him in an anomalous position in his relations with officers and men of the navy, with officers of the army and other military organizations, and with civilians." They say also of the recommendation that the Surgeon-General and three other medical officers should have the rank of Rear Admiral, that there is no good reason "why flag rank should not be open to officers of the Medical Corps of our navy as in the navies of the other great nations of the world, or why they should be denied a just share in the higher honors toward the end of a lifelong service in the navy."

The publication of these suppressed reports of the sub-boards of the Navy Personnel Board at this particular time is interesting, if not significant, in view of the controversy regarding the medical command of hospital ships which is said to have led to the resignation of Admiral Brownson as Chief of the Bureau of Navigation. The immediate occasion for Admiral Brownson's resignation has not been announced officially, but it is said to be the order assigning Surgeon Charles F. Stokes to the command of the Hospital Ship *Relief*, in spite of the strong protest of the Chief of the Bureau of Navigation against giving command of a ship to a staff officer without military rank or title. This order has brought the dispute over both these subjects to an acute stage.

That the members of the Medical Corps shall be in command of the hospitals of the navy is a statement that can admit of no question. They are held responsible for the care of the sick and wounded, but the idea of responsibility without authority is farcical. The comparison of the medical histories of the Hispano-American and the Russo-Japanese wars is a little hackneyed, but its lessons must not be forgotten. If it is admitted that a naval hospital on shore should be in command of a medical officer it is evident that a hospital on sea should be under the same control. It is not contended that the navigating officer of a hospital ship should be a medical man, though it is as reasonable that he should be as that a line officer should have authorty over the medical treatment. To the civilian mind it seems perfectly feasible to entrust the navigation of the ship to officers of the line while the supreme command rests in a medical officer of superior rank. And this could be if the medical officers had military rank and title equally with the officers of the line, as the sub-board recommends. The *Relief* was formerly an army hospital ship and then was always in command of an officer of the medical corps. Furthermore, as Surgeon-General Rixey has recalled in discussing the appointment of Surgeon Stokes, a joint board of army and navy medical officers, convened by Executive order more than a year ago to attempt to unify the medical service as much as possible, recommended that hospital ships should be commanded by medical officers, and the recommendation was approved by both the Secretary of War and the Secretary of the Navy in general orders. The Japanese naval ships were first commanded by line officers, but later the command was turned over to the medical corps with most satisfactory results. It will, no doubt, ruffle the dignity of some of the young men just out of Annapolis to be placed under the authority of medical officers of twice their years, but after they have recovered from the shock they will find that their dignity has received no fatal wound and that the sick sailors have a better chance of recovery and of an early return to duty when their treatment is not subject to revision by a layman.

A MODERN CORNARO.

"DIVINE sobriety, friend of nature, daughter of reason, sister of virtue. . . . It is the root of life, of health, of joy, of address, of skill, and of every action worthy of a noble mind." In such words did Luigi Cornaro, four hundred years ago, praise the virtue of abstemiousness, to the practice of which for forty years he attributed his hale and hearty condition at the age of eighty. At forty he was a man of ruined life, broken down in health, and condemned by his physicians to speedy dissolution unless he abandoned the habits of gluttony and irregular living which had brought him to this wretched state. After a struggle with his appetite he adopted the counsel of his medical advisers, reduced his daily allowance of food to twelve ounces, and within a year found his reward in the enjoyment of health of body and serenity of mind to which all his life he had been a stranger. "Divine mastication," sings Horace Fletcher to-day, and in less rhapsodical but no less fervent terms lauds his system of thorough chewing and of eating only when hungry, to the practice of which he

attributes the health and really remarkable power of endurance which he enjoys. Ten years ago he was a rejected candidate for life insurance, and to-day, at the age of nearly sixty, without special training, he is able to perform "stunts" which are far and away beyond the power of young athletes in active training.

In the *Popular Science Monthly* for December Professor Chittenden of Yale University publishes a report of certain tests of strength and endurance to which Mr. Fletcher was submitted under the direction of Dr. Anderson, director of the Yale gymnasium. One of the tests was made with the Fisher dynamometer, an instrument designed to measure the endurance of the calf muscles. The strength of the subject is first ascertained by one steady contraction and then the endurance is tested by contracting the muscles against three-fourths of the ascertained limits of his strength as many times as possible at intervals of two or three seconds. Mr. Fletcher's strength was found to be capable of lifting about four hundred pounds in this machine, and in the endurance test he raised three hundred pounds 350 times. The average record of 18 Yale students with the same machine was 87.4 lifts, the extremes being 33 and 175. Thus Mr. Fletcher, with the disadvantage of some forty years, doubled the best record of his youthful competitors. During this test the subject's pulse rose from 75 to 120, but fell within five minutes to 112, and at the completion of the test the hands were steady, and the control of the right foot and leg used in the test was normal. Other tests were made during six days, of quickly climbing 32 spiral steps, trunk raising from 50 to 100 times, trunk bending so as to touch the floor with the fingers without bending the knees 60 to 300 times, lifting 25-pound dumbbells 5 to 10 times, "running in place," that is, alternate knee lifting to the extreme possible height, for one minute at a time, and rapid extension of the arms upward, outward, and downward for three minutes. Neither during nor after these trials, Dr. Anderson reports, were there the slightest evidences of soreness, stiffness, or muscular fatigue, and "during the thirty-five years of my own experience in physical training and teaching," he adds, "I have never tested a man who equaled this record." Mr. Fletcher claimed to have done no training nor to have taken any strenuous exercise since February, 1907; the tests were made in June of the same year. Four years ago, after he had been following his masticating system for five years, Mr. Fletcher was submitted to tests similar to these later ones, and then, it was reported, he was "able to do the work of trained athletes and not give marked evidences of overexertion." Comparing the results of the two tests, Dr. Anderson says: "The latter tests, given in June, 1907, were more taxing than those given in 1903, but Mr. Fletcher underwent the trials with more apparent ease than he did four years ago. What seems to me to be the most remarkable feature of Mr. Fletcher's tests is that a man nearing sixty years of age should show progressive improvement of muscular quality merely as the result of dietetic care and with no systematic physical training."

It seems a little hard that a man who is able to give such remarkable proofs of physical endurance and of progressive improvement therein with increasing age should not be allowed his own pet explanation of the phenomenon. He attributes it to his habit of thorough mastication and automatic swallowing, together with abstention from food until driven thereto by the demands of hunger. Chittenden, however, dismisses this claim with a word and deduces from Anderson's report a proof of his own contention that the real requirements of the system, for protein especially, are only about one-half the amounts called for by the usual dietary standards. Haig, also, commenting in the *Edinburgh Medical Journal* for December upon the result of these tests, makes light of "Fletcherism" as a system and says that it increases power and endurance only because it leads to a diminished intake and a diminished formation of uric acid. "If the success of Fletcherism is due to the chewing," he says, "to what is the similar success of the vegetarians due?" He recalls a long-distance walking match held in Berlin in July, 1907, in which there were twenty-nine starters, fifteen vegetarians and fourteen mixed feeders. Of this number only six came in at the finish, and five of these were vegetarians, the sixth and last being a mixed feeder. The comparison is not very apt, for the tests were different in character, and Fletcher, moreover, is a mixed feeder and not in any sense a vegetarian. We have no record of any endurance tests by Cornaro, except that he lived to the age of 102 years, which is something of an endurance in general; but he, too, was a mixed feeder, his daily ration consisting of rolls, eggs, meat, and soup. The vegetarians, as such, are out of the counting, and the palm for endurance of life and muscular endurance must be given to the abstemious. The advocates of total abstinence from alcoholic beverages will find little comfort from the example of either of these enduring men, for Fletcher makes no pretense to anything more than temperance in the use of alcohol, and Cornaro allowed himself the generous amount of fourteen ounces of wine daily.

Even Chittenden's explanation is far from satisfying the sceptic. If abstemiousness is the only reason for his great endurance, why should Fletcher so far outclass in this respect all those living experimentally on Chittenden's half rations, and why should there not be hosts of his equals or superiors among the many submerged millions in this land of plenty who are chronically underfed—or normally fed according to Chittenden's dietary standard? Until it has been disproved, it is but fair to concede Fletcher's claim that good chewing is at least partly responsible for his condition; it is as worthy of acceptance as Haig's or Chittenden's, and as little proved by Fletcher's endurance tests. The true explanation of the phenomenon probably is that Mr. Fletcher is a somatic freak, comparable to the mathematical prodigies and other mental freaks. His endurance performances are so far ahead of anything on record as to put them outside of the normal and in the class of prodigies for which he is only in a measure responsible; his abstemiousness and his excellent digestion, dependent upon com-

plete mastication, have not created his powers, but have only developed and served to perfect the physical talents with which he was originally endowed above his fellows to an abnormal and so to say freakish degree.

The Prevention of Postanesthetic Pulmonary Complications.

In spite of the undoubted advantages that spinal anesthesia possesses in certain cases, and in spite of the efforts that have been made—particularly in Germany—to extend the indications for its application, it is clearly evident that for routine use the inhalation of ether still forms the most available method of securing insensibility to the pain of major operations. A great deal has been accomplished by means of special apparatus or methods of administration in making the induction of the anesthetic state less disagreeable to the patient and in diminishing the immediate dangers of the procedure, but the risk of postoperative pulmonary complications is still far from insignificant and demands every effort for its reduction. The suggestion of attempting partially to disinfect the mouth and upper air passages by means of washes and inhalations before the operation is not new, but the advantages of this precaution are reiterated with much emphasis by Otte in the *Münchener medizinische Wochenschrift*, December 10, 1907. Since 1900 no cases of ether pneumonia and very few instances of milder bronchial disturbance have occurred in the Osnabrück Institute of Midwifery owing, in the author's opinion, to the fact that on the evening before the operation, immediately preceding and following the anesthesia, and during the convalescence, the mouth is rinsed with an antiseptic solution and steam inhalations with thymol and salicylic acid are practised for a half hour at a time. By this means the mucous membrane of the respiratory passages is said to be rendered less susceptible to the irritant effect of the anesthetic and the secretion of mucus is much reduced. Importance is also attached to the manner in which the ether is administered. This is done by means of the Juillard inhaler, though any other would serve equally well if it possessed the cardinal requisites of permitting accurate control of the concentration of the ether vapor and of absolutely preventing the inhalation of minute droplets of ether. A further advantage claimed for the postoperative steam inhalations, which the patient is encouraged to practise as deeply as possible, is that they favor thorough expansion and aeration of the lung and therefore improve the pulmonary circulation. While such precautions add not inconsiderably to the details of preparation and after-care, they seem theoretically well founded and practically effective, so that the advisability of their more general adoption is worthy of consideration.

The Use of Sulphur in Dermatology.

Although recognized as one of the most valuable remedies for many skin lesions, sulphur is sometimes criticised as being somewhat unreliable in its action. While usually exceedingly effective, it at times falls short of what is expected of it in a manner not wholly explicable by the possible individual variation in different cases. Riecke (*Deutsche medizinische Wochenschrift*, December 12, 1907) ascribes this largely to the difference in the size of the sulphur particles contained in different preparations, the larger the crystals the less active being the application. Stich has investigated this matter and described in the *Pharmaceutische Zeitung*, No. 75, 1907, several methods of obtaining ointments in which the sulphur is in a state of extremely minute subdivision. The one of these that Riecke has found most satisfactory is made by freshly precipitating a solution of sulphurated lime and triturating the still moist precipitate with an ointment base in such proportions as to form a thirty per cent. ointment. Riecke states that this preparation is unusually satisfactory in the treatment of scabies, acne, seborrhea, and parasitic affections, and in fact whenever sulphur is indicated, its increased potency being due to the very minute state of subdivision of the active agent and the large proportion present. The ointment, it is stated, can readily be prepared by any druggist, and the attempt is being made to have it incorporated in the next edition of the German Pharmacopœia.

News of the Week.

Grip Epidemics.—Epidemics of grip of unusual severity have invaded the cities of Baltimore and Pittsburg, and in both places the number of persons ill is so great as to interfere seriously with the conduct of business, while the hospitals are crowded and the physicians overworked. In this city the number of cases is large, but the disease is of comparatively mild form. In Washington also the disease is widely prevalent.

Health Conditions in London.—The report of London's Medical Health Officer shows that for the County of London, with a population of almost five millions, the death rate for 1906 was only 15.1 per one thousand, which is lower than that of any city in England of over 200,000 population excepting Bristol and Leicester. It is also lower than that of Paris, St. Petersburg, Berlin, Vienna, Rome, Copenhagen, and New York. There is a marked difference between the rate in various districts. Hempstead's rate is 9.4 per thousand, while in Finsbury, which is one of the most crowded districts, the rate is 20.7. London shows the lowest infant mortality of all the towns excepting Bristol, but the deaths of children under one year old are 131 per thousand births, due mostly to intestinal disorders. There were no deaths during the year from smallpox, of which there were only 31 cases, the lowest record excepting in 1899. Scarlet fever, diphtheria, and whooping cough are decreasing, and typhus has almost died out. There were only 4 cases of it during the year, none of them fatal. Typhoid fever increased, and caused 290 deaths, as compared with 234 in 1905. The majority of the cases were traceable to the consumption of shellfish, especially cockles, and to the use of watercress. Pulmonary tuberculosis increased. There were 6,775 deaths from it, as compared with 6,622 in 1905. Cancer is also increasing, and was responsible for 4,589 deaths.

The New York Herter Lectures.—Professor Ernest H. Starling, Professor of Physiology in the University of London, will give the Herter Lectures of the year on the subject, "The Fluids of the Body," beginning January 6 at 4 P. M., and continuing at the same hour throughout the week at the Carnegie Laboratory of the University and Bellevue Hospital Medical College, 338 East Twenty-

sixth street. All interested are cordially invited to be present.

A Fund to Secure Christian Science Proselytes.—The officials of the Christian Science organization have announced Mrs. Eddy's intention of devoting the sum of $1,000,000 to the foundation of an institution to be known as "Mary Baker G. Eddy's Charitable Fund" and intended for the free instruction of the indigent in the principles of her cult.

Christian Psychology.—Bishop Samuel Fallows of the Reformed Episcopal Church of Chicago has enunciated the doctrine of what he terms "Christian psychology" by means of which he would have clergymen assist physicians in the treatment of such disorders as are amenable to influence by the patient's mental attitude. Among these he enumerates: Functional nervous disorders, hypochondria, sleeplessness, nervous dyspepsia, melancholia, mental depression, hysteria, neurasthenia, drug habits, want of self-confidence, irritability, worry, anger, fear, weakness of will.

Appendicitis Operation on Ocean Liner.—Another instance of abdominal surgery performed under trying conditions was reported when the Cunarder *Pannonia* arrived last Sunday from Mediterranian ports. A coal trimmer on December 23 manifested symptoms of acute appendicitis, and the ship's surgeon, Dr. J. Fraser Orr, decided that prompt operation was imperative. As there was a heavy sea on, the engines were stopped and the ship allowed to fall into the trough of the waves to lessen the pitching while the surgeon, with the aid of a medical assistant, removed an appendix that was found to be gangrenous. On reaching port the patient seemed in good condition and likely to have an uncomplicated convalescence.

Park Ambulance to Be Discontinued.—The Central Park ambulance that has been maintained by the city for twenty-five years is to be discontinued after January 1. Dr. Charles H. Goldsmith has been ambulance physician for seventeen years. The reason given by Park Commissioner Smith for abolishing the service is that the demands upon the ambulance did not justify the expense required for its maintenance. The average number of calls responded to is said to be about thirty-five a month.

Ambulance Accident in East New York.—A Bradford Street Hospital ambulance last Sunday was run into by a delivery wagon at the corner of Stone avenue. Both drivers were thrown from their seats and both horses ran away, but the surgeon, Dr. Michaelis, climbed out along the shafts of the ambulance, jumped astride the horse, picked up the trailing reins, and stopped the frightened animal. He then drove back to the scene of the accident, dressed the injuries of the two drivers, and proceeded to his original call.

Resignation of the Counsel of the County Medical Society.—Mr. Champe S. Andrews, who has been for many years counsel for the County Medical Society, has sent in his resignation and it has been accepted by the comitia minora.

Hebrew Charities Close.—The United Hebrew Charities, which gives assistance to about 40,000 persons annually, closed its doors temporarily last week because of a lack of funds. It is expected that the main offices, at 350 Second avenue, will be reopened on January 1, but the branches at 185 East Broadway and 149 Rivington street have been closed permanently. The trustees of the organization closed a third branch, at 91 Cannon street, about a month ago. The trustees decided a month or more ago that the resources of the Charities would permit of the expenditure of only $20,000 a month. That appropriation for December has been exhausted, and as a result the doors were closed for the remainder of the month.

Chicago Hospitals to Care for Emergency Cases.—It is said that the transformation of practically every big hospital in Chicago into an emergency institution for the care of the city's and county's patients is to settle the long-standing hospital problem. The county will thus foot the bills for all charity cases and the hospitals will collect from such patients as are able to pay for treatment. Under this plan the city would have more emergency hospitals available than under a plan proposed some time ago. It also would be relieved of the responsibility of paying the expenses. The county, it appears, is better able to pay such expenses than the city. The county is compelled by law to take care of all poor persons who need hospital and medical attention. It is said that many of the Commissioners of Cook County have already expressed themselves as favoring this plan, and it is considered certain that favorable action will be taken. A committee then will be appointed to arrange for the making of necessary contracts with hospitals. When this plan is carried out, the city still will be confronted with the question of a central emergency hospital in the down-town district. The suggestion that an emergency institution be maintained in connection with the Health Department may be acted upon favorably, as it would not interfere in any way with the county's plans for emergency hospital treatment.

Sydenham Hospital.—The following members of the Medical Board of the Sydenham Hospital resigned recently: Drs. E. Beer, H. Boldt, C. G. Kerley, L. La Fétra, S. Oppenheimer, G. Seeligman, A. Strouse, and A. Wiener.

Charges Against State Hospital Groundless.—The State Commission in Lunacy as the result of its investigation into the charges of brutality made against the attendants of the Manhattan State Hospital at Ward's Island has decided that the allegations were unfounded and has recommended that the pay of the attendants be increased.

National Association for the Study and Prevention of Tuberculosis.—The fourth annual meeting of this organization will be held in Chicago June 5 and 6, 1908. The organization of the sections has been arranged as follows: Sociological Section, Mr. Ernest P. Bicknell, Chicago, Chairman; Mr. Alexander M. Wilson, Chicago, Secretary. Clinical and Climatological Section, Dr. Henry Sewall, Denver, Chairman; Dr. H. W. Hoagland, Colorado Springs, Secretary. Pathological and Bacteriological Section, Dr. L. Hektoen, Chicago, Chairman. Surgical Section, Dr. A. E. Halstead, Chicago, Secretary. Section of Tuberculosis in Children, Dr. William F. Cheney, San Francisco, Chairman.

Advisory Tuberculosis Board.—Dr. Eugene H. Porter, Commissioner of the State Department of Health, has invited the following to become members of an advisory board to aid in the combat against tuberculosis: Dr. Thomas Darlington, Livingston Farrand, Homer Folks, and Dr. Alfred Meyer of New York, Dr. E. R. Baldwin of Saranac Lake, Dr. George W. Goler of Rochester, Dr. Willis G. MacDonald of Albany, Dr. V. H. Moore of

Ithaca, Dr. John H. Pryor of Buffalo, and Dr. William H. Watson of Utica. Governor Hughes has promised his assistance in securing an appropriation of $50,000 at the coming session of the legislature for the purpose of furthering the work.

American Sanatorium Association.—At the annual meeting of this organization held on December 14, the election of officers resulted as follows: *President,* Dr. V. Y. Bowditch of Boston, reelected; *Vice-President,* Dr. L. F. Flick of Philadelphia, reelected; *Secretary-Treasurer,* Dr. H. M. King of Liberty, N. Y.

Contribution to the Infirmary for Deformities and Joint Diseases.—At a benefit given at the New Circle Theater on Sunday evening, the sum of $3,500 was raised for this institution.

Southern Surgical and Gynecological Association.—Officers as follows were elected at the meeting of this organization, held in New Orleans on December 20: *President,* Dr. F. W. Parham of New Orleans; *Vice-Presidents,* Dr. W. F. Westmoreland of Atlanta and Dr. H. B. Fry of Washington; *Secretary,* Dr. W. D. Haggard of Nashville; *Treasurer,* Dr. Stuart McGuire of Richmond. Next year's convention is to be held at St. Louis.

Hunt County (Tex.) Medical Association.—Officers as follows were elected at the meeting of this organization, held in Greenville, Tex., on December 17: *President,* Dr. J. H. French; *Vice-President,* Dr. J. F. Arnold; *Secretary,* Dr. D. R. Waddle.

North Kentucky Medical Association.—At the meeting of this association, held in Walton on December 20, officers were elected as follows: *President,* Dr. B. K. Menefee of Walton; *Vice-President,* Dr. C. W. McCullom of Erlanger; *Secretary,* Dr. O. E. Senour of Union.

Creek County (Okla.) Medical Society.—This society has been organized with the following officers: *President,* Dr. Bronaugh of Mounds; *Vice-President,* Dr. Croston of Sapulpa; *Secretary,* Dr. Justice of Sapulpa.

El Paso County (Tex.) Medical Society.—This society has elected the following officers: *President,* Dr. W. H. Anderson; *Vice-President,* Dr. W. L. Brown; *Secretary,* Dr. Herbert Stevenson.

Kent County (R. I.) Medical Association.—The following officers were elected at the meeting of this association, held in East Greenwich: *President,* Dr. F. B. Smith of Washington; *Vice-President,* Dr. C. S. Christy of River Point; *Secretary,* Dr. W. S. Reoch.

Cass County (Neb.) Medical Society.—The following officers were elected at the meeting of this society, held in Atlantic on December 19: *President,* Dr. Weaver of Cumberland; *Vice-President,* Dr. Zook; *Secretary and Treasurer,* Dr. Emmeret of Atlantic.

Guernsey County (O.) Medical Association.—The election of officers for this society at its annual meeting, held in Cambridge on December 10, resulted as follows: *President,* Dr. T. H. Rowles; *Vice-President,* Dr. F. E. Bird; *Secretary,* Dr. Fred Lane; *Treasurer,* Dr. A. B. Hadley.

North District (Tex.) Medical Association.—At the annual meeting of this organization, held in Fort Worth on December 12, the following were elected as officers: *President,* Dr. J. M. Inge of Denton; *Vice-President,* Dr. J. W. Carey of Whitesboro; *Secretary,* Dr. H. L. Moore of Van Alstyne; *Treasurer,* Dr. A. W. Carnes of Hutchins.

Fire at the Hospital for the Ruptured and Crippled.—On Christmas eve a fire broke out in the playroom of the hospital where there was a considerable quantity of easily inflammable material to be used in the Christmas celebration on the following day. The hospital fire corps and the firemen of several companies that were summoned controlled the blaze before it had reached a point making it necessary to move out any of the patients.

Obituary Notes.—Dr. John C. Johnson of Blairstown, N. J., died on December 23, at the age of eighty years. He was graduated in medicine in 1850 and had continued in active practice since that time.

Dr. John Y. Hoffman of Reading, Pa., died suddenly on December 26 at the age of forty-nine years. He was a graduate of Jefferson Medical College and had practised in Reading for many years.

Dr. Frank B. Look of Martha's Vineyard, Mass., died suddenly of cerebral hemorrhage in West Tisbury on December 13 at the age of fifty years. He was graduated from Bowdoin College in 1885, and after serving as interne in the Hartford Hospital at Hartford, Conn., began practice in Middletown, Conn. He remained there until 1896 and then returned for some years to Hartford, Conn. Since 1905 he had been a resident of Vineyard Haven.

Dr. Fred W. Goodwin of Halifax, N. B., died on December 18 at the age of fifty-one years. He was a graduate of the London College of Physicians and Surgeons and had practised in Halifax for many years. He was president of the Halifax branch of the British Medical Association and Professor of Materia Medica at the Halifax Medical College.

Dr. Elmer J. Barney of Berlin, N. H., died on December 18 at the age of thirty-four years. He was a native of East Charleston, Vt., and was graduated from the Medical Department of the University of Vermont in 1905, since which time he had practised in Berlin.

Dr. Worcester E. Boynton of Lowell, Mass., died on December 15 at the age of eighty-three years. He was born in Warren, N. H., and received his medical education from New York University and the Massachusetts Medical College. He practised for a time in East Hopkinton, N. H., and then for a period of thirty-five years in Lawrence, Mass. Since 1896 he had been a resident of Lowell.

Dr. Elmer E. Goodwin of Haverhill, Mass., died on December 19 at the age of forty-two years. He was born in Berwick, Me., and received his medical degree from Dartmouth Medical School.

Dr. George W. Wilson of Montezuma, Ia., died on December 16 of nephritis at the age of sixty years. He was graduated from the University of Michigan in 1870 and had practised for many years in Poweshiek County.

Dr. Charles E. Lippitt of Berryville, Va., died on December 21 at the age of seventy-nine years. He was born in Alexandria, Va., and served through the Civil War as senior surgeon of the Fifty-seventh Virginia Regiment.

Dr. M. C. Cox of Lanford, S. C., died on December 18 at the age of seventy-two years. He had practised in Laurens County for over fifty years, and had served in the Confederate Army as a captain in Goodwin's brigade.

Dr. James H. Blake of Houston, Tex., died suddenly on December 16 in his sixty-first year. Dr. Blake was born in Brenhan, Tex., and was grad-

uated in medicine from the Hahnemann Medical College of Philadelphia in 1870 and three years later from the Medical Department of the University of Maryland. He had practised in Houston for over thirty years.

Dr. Louis R. Pierce of Newburgh, N. Y., died on December 29 of pneumonia at the age of forty-one years. He was a native of Binghamton and received his medical degree from the Long Island College Hospital.

Dr. H. A. Worley of Omaha, Neb., died on December 10, at the age of fifty-eight years. He was born in Cleveland, O., but received his early education in Davenport, Ia., and was graduated from the Iowa State University and the New York Homeopathic Medical College. He had practised in Omaha since 1871.

Dr. William K. Wood of Berkley, Va., died on December 11 of typhoid fever, at the age of thirty-two years. He was a native of Elizabeth City, N. C., and was graduated from the Baltimore Medical College about ten years ago. Since that time he had practised in Berkley and for some years had been the city's health officer.

Dr. R. J. Peare of Pleasanton, Kan., died on December 7, at the age of fifty-nine years. He was born in Ireland and was graduated from the Ann Arbor Medical School in 1869. In 1893 he removed to Canon City, Col., and five years later to Pleasanton.

Dr. Robert I. Thomas of Los Angeles died on November 21 at the age of ninety years. He was surgeon-major in the Civil war and for twenty-five years was government surgeon for the Sioux Indians at Fort Randall, S. D.

Dr. John Fay died at Altoona, Pa., on December 6 at the age of seventy-seven years. He was graduated from Jefferson Medical College in the class of 1855. He served as a surgeon in the United States Army during the Civil War. Subsequently he became a surgeon in the service of the Pennsylvania Railroad Company. On the organization of the Altoona Hospital he was made chief of the medical staff and he retained this position up to the time of his death.

Correspondence.

THE OPTOMETRY BILL.

To the Editor of The Medical Record:

Sir:—During the past few weeks I have received several letters of inquiry from different parts of the State concerning the proposed effort, as reported in the newspapers, on the part of certain opticians to secure the passage of a law creating the profession of optometry. I have thought it well to place my answer to these letters in a general way before the profession, urging concerted action against this effort to secure special privileges on the part of opticians, and know of no better way to do this than through the columns of the popular Medical Record.

The proposed Optometry Bill will probably be a more serious matter at the coming session of the Legislature than at any time in the past. In our hearing before the Governor in June, 1907, two points were raised which defeated the measure. The first was that a board of examiners was authorized, appointed by the Regents, from lists nominated by the Optical Society of the State of New York, and the second that optical schools were authorized, maintaining standards satisfactory to the examining board. We called attention to the fact that these two provisions permitted the Optical Society, which is a voluntary, irresponsible body, to dictate to the State in the appointment of the examining board and also in the determination of standards, defects which existed in the old medical law and were remedied in the new medical law which the present Governor had recently signed.

We who have made a study of this subject were confident that these two errors were vital, and, although the Governor seemed to doubt their importance when presented to him, they were the only two objections he raised in the memorandum filed with his veto. Other arguments were presented at the time to show the dangerous character of the measure, and they are the arguments which must be raised in opposition again, for the bill will doubtless now be more carefully drawn, and our contention must be narrowed down to what I have always considered to be the main issue, namely, that it will be neither wise nor safe to grant to any body of individuals the right to practise, even in a limited way, what is now considered a part of the practice of medicine, unless a prerequisite shall be a compliance with the medical laws of the State. The advocates of the bill will claim, as in the past, (1) that opticians have been doing this work from the time glasses were first used, without molestation or interference, and that they have brought the science of optometry up to its present condition of accuracy and refinement; (2) that they have become established in practice, have large capital invested, and therefore have vested rights; (3) that because of the increased demand for eyeglasses incompetent and unscrupulous people, calling themselves opticians, travel about the State, imposing on the credulity of farmers and others, especially in thinly settled sections, charging exorbitant prices for their wares and even doing harm to the eyes of their dupes; (4) that the opposition to the enactment of the law they desire comes from oculists; (5) that medical colleges devote very little time to the teaching of this subject and in consequence physicians are graduated who have comparatively little or no knowledge of optometry; who do not know how to examine an eye and adjust glasses thereto, and yet are authorized by law to do this work.

These are the arguments dwelt on in the past, and to my mind they should be met fairly and squarely, without prejudice, and the whole subject decided on its merits. The legislators and the Governor are sworn to protect the interests of the State and they will be actuated by this purpose in enacting laws. If the arguments of the opticians who are demanding this bill outweigh those in opposition, the optometry law will be enacted. Let us consider the claims made by the opticians and how we should answer them.

First: That they have been doing this work from the time glasses were first used, without molestation or interference, and have brought the science of optometry up to its present condition of accuracy and refinement. It is true that opticians have been storekeepers, dealers in optical goods, and possibly grinders of lenses for many years, and so far as I know there is no desire on the part of anybody to molest them or interfere with them now if they will adhere to their calling in these respects. The adjusting of lenses when help is needed in advancing age has always been done by opticians to a certain extent, but this does not require ability to diagnose diseased conditions or departures from the normal. A person who thinks he needs glasses has a perfect right to go to a store where glasses are sold and the storekeeper, if he helps his customer in the choice of what seems most comfortable, ought not to be denied the privilege of so doing. And the same might apply with equal force to the shoemaker, the corsetmaker, and so on. For opticians to undertake, however, to make an opthalmoscopic examination of the interior of the eye, to test the ocular muscles, and prescribe prisms for muscular insufficiencies, when these defects may possibly be due to disease of the spinal cord; to prescribe glasses for the relief of headaches which may be due to brain tumors, Bright's disease of the kidneys, etc.; to undertake the treatment of strabismus by the use of lenses, even charging a fee for their examinations and advice over and above the cost of glasses, as the very advocates of this bill are now doing, approaches very closely to the practice of medicine as defined by the present medical law. When they claim any credit for the advancement of the science of ophthalmology—which is the proper term to apply to work of this kind—opticians cannot really expect anyone with knowledge of the facts to endorse them. The development of the science of ophthalmology, beginning with Donders and Helmholtz, has been the work of physicians and the practice should not be separated from the medical profession.

Second: That they are established in business, have large capital invested, and therefore have vested rights. I have no idea what "vested rights" may include in its fullest significance, but if the investment of capital in business that may be harmful to the community constitutes "vested rights" then the quack, charlatan, criminal abortionist, professional gambler, and others may make the same claim. To my mind there can be no "vested rights" so great as to outweigh the "rights" of the people of the State, and if the legislators, elected to protect the rights

of the people, are convinced that the practice of optometry, as at present carried on by opticians, is inimical to the interests of the people, any law passed by it to properly safeguard those interests is not likely to be contested on the ground of being unconstitutional.

Third: That because of the increasing demand for eyeglasses, incompetent and unscrupulous peddlers calling themselves opticians travel about the State, imposing on the credulity of farmers and others in thinly settled sections, charging exorbitant prices for their wares, and even doing harm to the eyes of their dupes. Of course this is true. People are fond of buying "gold bricks" and it is astonishing how intelligent people will listen to the most outrageous yarns told by fakirs of all kinds, and yield to their persuasive arguments, when a reputable licensed physician might talk himself hoarse without convincing them in the least. This is so old and so true that it has become historical, but that is no reason for the enactment of special laws to govern every new phase of this confidence game. There are laws enough now on the statute books which are never enforced without adding to the list because some one has suddenly discovered a fact long ago known to exist.

Fourth: That the opposition to the enactment of this law comes chiefly from oculists. It may seem unfortunate that physicians who devote themselves to the practice of ophthalmology should be the ones who have directed the opposition to this measure, because it has given the advocates of the bill the opportunity to point to their opponents as evidence of the truth of their contention that commercial reasons and the fear of competition prompted the opposition. It is perfectly natural that physicians who practise this specialty—or optometry, as the friends of the bill seem to prefer—should be the ones to point out the dangers of the measure. They of all others know the importance of the work, and they of all others have knowledge of the disastrous consequences of opticians adjusting lenses to the eyes when proper attention on the part of physicians might often have prevented blindness or even prolonged life. The charges of personal interest and of the desire to limit competition have never strengthened the cause of the advocates of this bill. The claim is absurd and does not influence many of the legislators. The physician with his superior training and facilities need not fear the competition of any person with less training, for in the end the best man wins. The one who suffers is the man practised upon by the partially educated practitioner. We need not waste time answering arguments or statements challenging our motives, for the facts speak for themselves. Everybody knows, or ought to know at least, that it would be a most unfortunate thing to divide the practice of medicine into specialties and exact any less preparation for them than is required of all physicians. To create doctors of optometry, of gynecology, of dermatology, of hydropathy, of osteopathy, of allopathy, of homeopathy, and so on, would be disastrous to the dignity and integrity of a learned profession, to say nothing of the dangers to which it would expose the public at large. We who have been through the preparation know that one cannot be proficient in special lines who has not been educated for the general practice of medicine. We know only too well that with the best preparation possible we often feel lamentably incompetent.

Fifth: That medical colleges devote very little time to the teaching of this subject and in consequence physicians are graduated and licensed with comparatively little knowledge of optometry, who do not know how to examine eyes for glasses, and yet are permitted to do this work. This opens up a large field for discussion, but that it is used only to blind the legislators is evidenced by the fact that the opticians, if they are granted their desires, are willing to allow an exemption of all physicians in their bill, despite the charge of their ignorance. The course of instruction in undergraduate colleges is not supposed to fit a graduate to practise as an expert specialist in any line. A doctor just graduated from his medical college could not be expected to perform a cataract operation, or fit lenses to the eyes skillfully, any more than he could operate for an abdominal tumor, for appendicitis, or for mastoid or brain abscess. The course of training in a medical college includes a thorough training in the fundamentals of medical practice. The special lines, including the fitting of glasses and the performing of surgical operations, are taught, but the student does not get the training necessary to make him skillful in any special branch in his college course. The mastery of these details is altogether unnecessary for the physician who enters into family practice. It is impossible for one man to become proficient in all special lines and the man who tries to do it generally ends by being proficient in none. The doctor who desires special training takes up this work in the post-graduate schools now existing in all large cities. Despite the statements of certain people, who are ignorant of the facts, there are many places in this country where physicians can learn all the details of work in special lines. The physician who desires to take up the study of optometry has open to him the various post-graduate schools, as well as the more desirable special institutions, like the Manhattan Eye, Ear, and Throat Hospital, the New York Eye and Ear Infirmary, and other places where efficient schools of instruction are maintained for graduates in medicine.

The question must naturally arise, Is there need for any legislative action in this matter? I believe there is great need for a positive and comprehensive law governing the practice of optometry, so called. The influence of defective eyes on the growth and mental development of children is a subject about which argument is hardly necessary in these days. Educators all over the world are talking and writing about it until the time has arrived when its importance is much more likely to be overestimated than otherwise. The relation of optical defects and muscular imbalance to mental development, epilepsy, chorea, and various other reflex phenomena is so important, and the whole subject is so intricate and variable, that the most skillful and intelligent physicians are not yet entirely agreed on the exact relation of cause and effect. The boards of education and of health are interested to the extent of urging appropriations for the investigation and study of the subject, but so far I have not heard of one who has probed deeply into the subject who would be willing to say that any person other than a physician would be competent to pass on the questions and problems involved.

This law advocated by the Optical Society would give to the optician, whose knowledge at best would be of the most superficial character, the right to present his claim for the position of examiner of the eyes of children in our public schools, if such a position was created. How could the board of education or of health refuse to recognize the right of an optician to such a position when the State, by legislative enactment, had given him the right to do the work this position would call for?

The optician has a most important position, very similar to that of the druggist. He should be controlled by law and compelled to demonstrate his ability to fill prescriptions written by physicians, as the druggist is. There are many storekeepers, jewelers, and others who pose as opticians, who have no knowledge of the mechanical work opticians should be able to do. In consequence of this the benefit which should be obtained from glasses prescribed by physicians is often not obtained because of the bungling work of the one who fills the prescription.

My experience leads me to believe that the lawmakers are anxious to do something to regulate this practice. At the last session they passed a medical bill and the Governor signed it, because the medical profession and the Department of Education united in drafting it. In consequence the State of New York has a medical law more nearly ideal than many thought it possible to obtain. If those who should be interested in this optometry question would unite the same result could be accomplished. In the first place the great universities with medical departments should take the lead in obtaining such legislation. Optometry is the most important and difficult part of the work ophthalmologists are called upon to do. It deals with defects, the recognition and correction of which may determine whether an apparently incorrigible boy in public school shall become a criminal or a useful member of society. It deals with possible conditions in the eye the recognition of which may result in the treatment of disease in other parts of the body, prolonging perhaps the life of a father whose death might mean a family becoming a public charge. It deals with muscular defects the correction of which may mean a life of comfort and usefulness to one who might otherwise become a confirmed invalid or epileptic. Its study involves problems, compared with which the surgical treatment of the eye, the removal of cataracts, of tumors, and so on, is the veriest child's play, for these require only a certain amount of manual dexterity and not necessarily extensive knowledge.

There are hundreds, perhaps thousands, of men studying medicine in our medical colleges to-day who will some day become specialists in eye diseases. If when they arrive at that time they find themselves face to face with men calling themselves doctors of optometry, who, with a trifling knowledge of optics, and possibly no knowledge of anatomy, physiology, chemistry, bacteriology, and so on, which the doctor of medicine has spent years of hard grind and privation to obtain, have the legal right to to do the most important and intricate part of the work

of the physician, the man who has spent his time in the medical college will be apt to consider that he has wasted years of his life. And if the optometrist can become sufficiently proficient with his moderate amount of preparation the doctor of medicine has wasted his time.

So I believe it is up to the deans of medical colleges, the professors of ophthalmology in these colleges, and the chancellors of the universities of which these medical colleges are departments, to take this matter up and give it careful study. If the medical education is not necessary for the intelligent practice of optometry, then let us cease our contention; if a medical education is necessary, then let us demand that the practice be limited to physicians. Of this I am sure: If the educators of the State, the State Education Department, and the medical profession will unite in their petition to the Legislature a law can easily be enacted which will be just to all concerned.

(From Our Special Correspondent.)

SCIATICA—MEDICAL INSPECTION OF SCHOOL CHILDREN—BRISTOL INFIRMARY AND PLEURAL APPOINTMENTS—A "BROWN DOG" ÉMEUTE—TROPICAL SCHOOL'S MEDAL—NURSES' DIPLOMAS—OBITUARY.

LONDON, December 13, 1907.

SCIATICA is so troublesome a malady to both doctor and patient that any attempt to elucidate its origin is pretty sure to interest every practitioner. A paper at the Medical Society of London on its relation to hip-joint disease was read by Dr. Ironside Bruce and elicited a brief discussion. Dr. Bruce showed skiagrams to prove that certain changes in the hip joint are frequently present in cases of sciatica. The results of gouty or other inflammations, he said, could be demonstrated by radiography and it would be well to investigate in this way all cases of sciatica. He exhibited five such skiagrams presenting articular changes from cases with the typical symptoms of sciatica. He did not contend that all cases showed these changes—indeed, the five instances had been obtained from twelve cases. In one of them the head of the femur had been excised and showed the changes usually considered to be characteristic of arthritis deformans. He did not suggest that such changes were constant, but he was convinced that routine examination with *x*-rays of all intractable cases would show that in a large proportion the sciatica was a symptom of chronic rheumatic arthritis.

Dr. de H. Hall remarked that such examination would be helpful in all cases of pain along the course of the sciatic nerve.

Dr. Fortesque Fox expressed his satisfaction with the old view that sciatica was almost always a pure neuritis and had no connection with bones or joints. He admitted, however, that there were cases following injury to joints which formed a secondary class.

Points mentioned by other Fellows were that the diagnosis between the nerve affection and hip-point disease should be attempted; that exposure and incision of the nerve had given immediate relief; that further investigation was needed to exclude disease of the lower part of the vertebral column; that the question whether muscular wasting indicated joint disease required clearing up, and that the pelvic condition was of some importance in obstinate sciatica.

In reply to a question, Dr. Bruce said the patient from whom the head of the femur had been removed was now free from pain and his limb was fairly useful.

The medical inspection of school children has, since the recent Act, been the subject of discussion and even disputation among those interested in either education or public health. Among the disputants were those who looked with suspicion on the Board of Education, some even who were prepared to say that nothing but organized public opinion would overcome the opposition of the permanent officials. The *British Medical Journal* claimed, as usual, the credit of inducing Parliament to pass the measure and as soon as it was passed made an unjustifiable attack on the Board for not appointing its nominee to the medical officership. The tone has changed of late, seeing that the action of the Board so far has secured the approval of almost all the organs of public opinion.

The Board decided to appoint as its own adviser a prominent medical officer of health rather than to initiate a new class of medical officers *ad hoc*, and in a memorandum lately issued for the guidance of local authorities commends this course for adoption. The plan seems the most natural. The Medical Officer of Health will find the additional duties will really facilitate his work in connection with the spread of infectious diseases; he has an interest in children of school age, which is manifest in almost every report of his work, to say nothing of his duties in regard to the school buildings, their ventilation, drainage, and general sanitary conditions, and the outbreaks of measles, scarlet fever, diphtheria, etc., which so often start among the school children.

The memorandum referred to above is of a preliminary nature and deals almost entirely with the new Act at its initiation, for it comes into force on the 1st of January. It points out the respective functions of the Board and the local authorities as defined by the Act. It states that the Board has decided that not less than three inspections during the school life of the child will be necessary; that the inspection is to be conducted in school hours, on school premises, and in such a way as to interfere as little as practicable with school work. Each inspection is to take account of the following matters: (1) Previous disease; (2) general condition and circumstances, height, weight, nutrition, cleanliness, as well as clothing; (3) throat, nose, and articulation; (4) external eye disease and vision testing; (5) ear disease and deafness; (6) teeth; (7) mental capacity, normal, backward, or defective; (8) present disease or defect.

A disagreement between the committee and the staff of the Bristol Royal Infirmary which has gone on for some weeks has been happily closed by a compromise accepted on both sides. I do not propose to discuss it so far as it relates to any local conditions, but will refer to the chief point involved, as it affects the profession everywhere. The committee desired to secure the exclusive services of their staff and to effect this proposed to alter the regulations so as to exclude them from accepting professional posts at other institutions. That is an intelligible wish and might be supported by various arguments. But the committee seem to have thought they could make a rule of that sort retrospective—a thing one would scarcely expect could be proposed or accepted. The staff naturally declined to be placed in such a position and much ink was shed in the conflict. Now it is happily ended and one may consider the question whether it is desirable for hospital physicians and surgeons to hold plural appointments. Something—often a good deal—may depend on the duties involved and of course something on the amount of work demanded by each. In London we have men serving a general and a special hospital and occupying other posts as well. In some cases, where there is great energy and the demands of private practice are not too heavy the plan works well, but in others I must admit there are defects. Men attempt too much for their strength and suffer in reputation and health. Another point, as affecting the profession apart from individuals, is that the pluralists are depriving others of the opportunities they look for. There are many young men who have attained a distinction which should render them eligible for any staff, but who have little prospect of such a position, simply because all the offices are occupied by their seniors. Some of the latter hold two or three, or even more, posts, any one of which the waiting men would gladly take. It is a fact, too, that some of our institutions have been established by such energetic young men or on their behalf, and the multiplication of these smaller hospitals is by no means desirable. From this it is clear that restriction to one appointment might be generally beneficial and any well-managed hospital could afford work enough to satisfy the zeal of its staff.

Some medical and other students having indulged in a raid on the "brown dog" at Battersea and subsequently in a procession to Trafalgar Square have come into collision with the police. You may remember that the brown dog in question is a statue erected by antivivisectionists in memory of the alleged victim, the falsehoods concerning which cost Mr. Coleridge and his supporters £2,000 as damages for libel. This libel is repeated in the inscription on the statue, which declares the dog was "done to death in University College," and that it "endured vivisection extending over more than two months," etc., etc. The raid on the memorial was successfully resisted by the police. But this week a meeting in Trafalgar Square was planned, a large crowd assembled, interfering with the traffic, and the police arrested several students and some passengers who could not make their way through the crowd. Some fines were inflicted on the leaders, others were discharged with the unfortunate passengers who had been arrested by mistake. Some of the newspapers have found good sensational copy in the rather silly escapade and talked of it as a serious riot, blaming the students, who numbered about a dozen, for disturbing the public peace. Yet these organs have no censure for the provocative inscription nor for the Battersea Borough Council, who actually presented the site for the statue.

On the other hand there are a few writers who have

pointed out that the whole blame should rather be laid on those who erected the statue and the Borough Council, for what is in fact a direct provocation to a breach of the peace.

It is pointed out that if Mr. Coleridge provoked a breach of the peace with a flag inscribed as the statue is inscribed it would be the duty of the police to take away the flag and if necessary to arrest him as the cause of the disturbance. It is remarkable, if such be the law, that the police should have interfered with a few students, though they protect the processions of working men.

The Liverpool School of Tropical Medicine has conferred on the Rt. Hon. Joseph Chamberlain the Mary Kingsley medal founded in memory of Miss Kingsley for presentation to those who have specially distinguished themselves in the amelioration of health conditions in the tropics.

Princess Christian, as president of the Royal British Nurses' Association, presented the diplomas to the first batch of successful candidates in the examination recently held by the Association under its charter. It is expected that this diploma will take precedence of the various certificates of training that have been commonly issued by various hospitals.

The death of Dr. C. R. Drysdale in his seventy-eighth year recalls to many an ardent worker for all he thought good for the profession and a zealous advocate of changes which he thought would promote the happiness of the people. He was many years physician to the Metropolitan Hospital and the West London Consumption Hospital and his surviving colleagues know how faithfully he worked with them. As physician to the Rescue Society he also did much good work. He wrote many papers for societies and journals. For the latter numerous leaders and unsigned reports. He published a work on syphilis, on which he was an authority, and another on prostitution medically considered. He supported the doctrine of Malthus and some other rather unpopular theories. He was F.R.C.S., as well as M.D. and M.R.C.P., an alumnus of University College, and spent some time in Paris under Ricord.

OUR CANADIAN LETTER.

(From Our Special Correspondent.)

MEDICAL STUDENTS AT THE DIFFERENT COLLEGES—PSYCHIATRIC CLINIC TO BE ESTABLISHED AT TORONTO—PROPOSED JOURNAL OF THE CANADIAN MEDICAL ASSOCIATION—DEATH OF DR. BAYARD, ST. JOHN, N. B.—THE M'GILL COLLEGE BUILDING—FEES FOR LIFE INSURANCE EXAMINATIONS—THE ACADEMY OF MEDICINE AT TORONTO—HONOR TO DR. GEIKIE.

TORONTO, December 21, 1907.

THERE are seven universities in Canada and eight medical colleges. The number of medical students this year is about 2,000, distributed as follows: Halifax Medical College, 100; Laval, Montreal, 325; Laval, Quebec, 100; McGill, Montreal, 425; Queens, Kingston, 325; Toronto University, 650; Western London, 100; Winnipeg Medical College, 100. Toronto, McGill, and Queens have adopted the five years' course. No one can be licensed to practice medicine in the province of Ontario until a five years' course has been taken. This law will probably be soon in force in every province. There are now 6,000 medical men in active practice in Canada. The great need is for a common registration standard for the whole Dominion on somewhat similar lines to that adopted in Great Britain. The question is now being discussed and there is no doubt that in seven of the provinces the sentiment is strongly in favor of establishing a Dominion registration board. Quebec is the only province in Canada that offers opposition to the scheme.

Steps have been taken to establish in connection with the new General Hospital at Toronto a psychiatric clinic, similar to that at Munich, for the treatment of acute cases of insanity. The Ontario Government during the past year appointed a commission to visit Europe and prepare a report on the best modern methods for treating and caring for the insane. The report of the commission has just been issued and action will no doubt follow without delay to carry out many of the recommendations made. The enlargement of institutions set aside for the care of chronic cases and the limitation in the size of the hospitals for acute cases constitute the prominent features of the report. The success of the methods of Kraepelin at Munich is spoken of in terms of the highest commendation, and the methods thus observed will be followed as far as practicable in the new psychiatric clinic to be established at Toronto.

Dr. William Bayard, said to be the oldest practising physician in the world, died December 17, at his home, St. John, N. B., aged ninety-four. Last August Dr. Bayard celebrated the seventieth anniversary of his entry into the medical profession. On that occasion Edinburgh University, of which he was the senior graduate, sent cordial greetings, and the Maritime Medical Association presented him with an address. For the past sixty-seven years Dr. Bayard has practised in St. John, of which city he has always been one of the most prominent and highly honored citizens. The General Hospital, which he founded in that city, is his chief monument. He was a past-president of the Canadian Medical Association and deservedly held a high place in the respect and esteem of the whole profession.

The question of establishing a journal for the Canadian Medical Association is at present being freely discussed. There are at present in Canada seven English and three French medical journals published monthly and circulated among 6,000 physicians. The new constitution of the association aims at the establishment of a journal, and the question of its probable success seems most debatable. Several solutions of the problem are suggested; one of these is that all the existing journals should merge their interests in one national publication. The expense of such an undertaking seems a formidable obstacle to such action, but the committee having the matter in hand is composed of medical men of zeal and earnestness and their report at the meeting next year will be awaited with considerable interest.

The new building for McGill Medical College at Montreal is to have many features that will be of the highest advantage to students and professors. It is calculated that the cost of the new building will be not less than half a million dollars. The location is most suitable, being so close to the Royal Victoria Hospital that professors and students can pass from classroom to hospital ward with a facility that is certain to be appreciated. The general plan is simple, consisting of a central block facing towards the campus and connected on each side with pavilions running parallel with the streets on either side. The whole equipment will be the best obtainable, and the museum and library will be so arranged that the danger of destruction by fire will be reduced to a minimum.

The fees for life insurance examinations in Canada have been receiving considerable attention recently. In many of the large centers the medical men have taken a firm stand and agreed that the fee for medical examinations made for life insurance shall never be less than five dollars. Most of the life insurance companies doing business in Canada have agreed to pay the fee thus fixed as being the minimum one for such work.

The Academy of Medicine recently inaugurated at Toronto promises to be most successful in every respect. The membership is large and represents every section of the city. Toronto has over 450 medical men, and a large majority of these have been enrolled as members. The sectional meetings are well attended and the program for the season has been so arranged that different evenings have been allotted to symposiums on different subjects in medicine and in surgery. The formation of the Toronto Academy of Medicine is a distinct step in advance and its privileges are likely to be highly prized by the whole profession. It is well located in the Queens Park and in a building that is large and commodious.

Dr. Walker B. Geikie of Toronto, founder of Trinity Medical College and its dean for twenty-five years, has been honored by Queens University, which recently conferred upon him the degree of LL.D. in recognition of his long and faithful services to medical education. His many years of laborious and successful discharge of his duties as a medical professor and his having cooperated in founding one of the best known medical colleges in Canada lead his many friends to feel that the honor has been worthily bestowed. The life-work of Dr. Geikie covers the most interesting period in the history of the medical profession in Canada. His work as a professor commenced in 1865 and among the members of the first graduating class of Trinity were several who have become leaders in the profession. Prominent among these was Prof. Wm. Osler, now Regius Professor of Medicine at Oxford. During his many years of consecutive work as dean and professor, Dr. Geikie was ever intense in his devotion to the cause of medical education in Canada.

Moving Pictures and Eyestrain.—The authorities of Berlin have instituted war against moving-picture theaters, of which there are over two hundred in the city. The health department holds that the jumping movement of the film is injurious to the eyesight, and since the shows are patronized to a great extent by children, disastrous results may be foreseen.—*The Physician and Surgeon.*

Progress of Medical Science.

Boston Medical and Surgical Journal, December 19, 1907.

Debility in Jewish Patients.—H. Morrison has made observations on the Hebrew patients applying for treatment at the Massachusetts General Hospital. He finds that debility is a common condition among them. As a rule it is temporary, but apt to recur. The prevalent symptoms are pain, constipation, and apprehension. The etiology of these debilitated conditions is to be traced to the peculiar circumstances under which the Jews have lived and still live in eastern Europe. Here in America the economic strain during the early years after arrival is an important factor. Debility is especially common among the Jewish women of the immigrant class, because the economic strain weighs very heavily on them. With them, also, imitation and tradition and the ease with which medical advice can be obtained are factors to be considered. These debilities are peculiar not to the Jew, but to the abnormal conditions under which he has been living. As soon as he is relieved from these conditions his symptoms are not different from those of other races. Finally, in the treatment of the cases considered it is well to bear in mind the importance of the old sentiment, "not the disease only, but also the man."

New York Medical Journal, December 31, 1907.

Pathology of Icterus Neonatorum.—A. Graves believes that both the liver and the disintegration of the maternal erythrocytes stand in a causal relation to this affection, which is in a certain sense physiological. The disintegration referred to is nature's method of supplying iron chromatin in sufficient quantity to enable the infant to continue the hematopoetic function on its own account and is accomplished in the following manner: In the hematopoetic organs of the new born, along with the formation of erythroblasts, some special body is formed, a cytolysin or hemolysin, which dissolves in the plasma and imparts to the latter globulicidal properties for erythrocytes other than those elaborated by himself, thence the total disintegration of maternal red cells. Now, if the formation of this globulicidal substance goes on at a normal rate, the disintegration of maternal red cells will go on at the same rate and the liver will not be suddenly overcharged with hematic pigment; but should the formation of this cytolysin go on with unusual rapidity, the contrary will happen, the liver will be overloaded with pigments derived from the disintegrated blood cells, the activity of hepatic cells will be overtaxed, and they will elaborate a surplus of biliary pigments. Thus the question is finally reduced to a disturbance of the equilibrium between katabolism and anabolism in this particular function of blood making. Through some cause, so far unknown, the cytolysin becomes more abundant, more red cells are destroyed at a time, more hemochromatin is stored in the liver than can be used up in the process of blood making, and the surplus actuates the hyperactivity of the liver cells which transform more blood pigments into bile pigments. As to the absorption of the surplus of bile pigments which finally causes the jaundice, three possibilities are present: First: As the terminal capillaries which surround the hepatic cells constitute a portal system, the intravascular and perivascular pressure equals zero. Now, if the hepatic cells are overfilled, the pressure within the bile capillaries will forcibly raise after a time, and the biliary pigments will penetrate into the lymph spaces and reach the general circulation through the thoracic duct. Second: Should we assume an increase in the viscidity of the bile duct due to a state of saturation with biliary pigments, the possibility of temporary plugging of the bile capillaries might be considered. In this case the chances of absorption of the bile through the lymph spaces are evident. Third: Another way of absorption, peculiar to the new born, is through the ductus venosus, as pointed out by Quincke: The flow of bile into the intestines not being impaired in icterus neonatorum, but rather increased, part of it is reabsorbed, gathered into the portal vein, and partially poured into the vena cava through the ductus venosus, which remains unobstructed during the first few days of extrauterine life.

Quinine Sulphate.—J. Y. Shearer relates some facts impressed on his mind by forty-five years of medical practice with relation to the effects and properties of quinine sulphate. He regards large doses of morphine sulphate as the proper antidote for quinine toxemia. The author regards quinine as a tonic, stimulant and antipyretic, or depressant. In pneumonia he gives from ten to thirty grains at noon and at bedtime a large dose of thirty to forty grains. He claims to have repeatedly forestalled the crisis by this method. Similar large doses will, he claims, cure hematuria, which he does not believe is ever due to malarial fever except in the more or less neurasthenic, and then only when small doses of the drug have been administered. Small doses frequently repeated may produce convulsions, which the same drug in a thirty to forty grain dose will control. The same reversal of effect from increase in dose has been observed in uterine hemorrhage. In ten to twenty grain doses every evening, alternating the quantity, has apparently cured gastric ulcer. A like result has followed in chronic diarrhea, the most obstinate cases yielding "without even as much as a waver," and again quinine sulphate, ten and twenty grains, alternating every evening for ten days, then ten grains every evening, then ten grains every other evening, for equal periods, and finally ten grains once or twice a week, then eat and drink what tasted best. In syphilis the following rules for administration are given: Primary stage, ten grains three times a week for two months, then twice a week for four months; secondary and tertiary stages, ten grains every evening for one month or six weeks, then twice a week for four months. In this way the author alternates during the entire specific treatment, with quinine sulphate for six months and rest for an equal period intervening.

Etiology and Treatment of Thrombosis.—Basing their views on studies of the coagulation of the blood, and examining mainly the blood of convalescent typhoid patients in whom the dangers of hemorrhage have been passed, H. A. Duncan and G. M. Illman conclude that the most common predisposing cause of thrombosis is the absorption of tissue juices into the circulation and the active cause is the increased coagulability of the blood. Blood which is received from a vein through a cannula into a glass lined with paraffin will not clot because no tissue juices are allowed to mix with the fluid. The authors believe that this absorption of tissue juices into the circulation occurs after a severe hemorrhage. In the infectious diseases the volume of blood is depleted by high fever, profuse sweating, diarrhea, internal hemorrhages, and here again the body juices are absorbed into the general circulation. Almost every delivery is accompanied by at least a slight loss of blood, often quite a decided loss. This is especially true of the primipara, where lacerations are more apt to occur. The authors have found that a high calcium content of the blood does not always mean a quick coagulation, and vice versa. They believe that in all medical or surgical conditions in which hemorrhage proves a factor, the coagulation of the blood should be carefully observed and at the first indication of increased coagulability prompt prophylactic treatment should be instituted. The blood-vessels should be kept well filled by encouraging the patients to drink water freely, by hypodermoclysis and enteroclysis, and by the administration of citric acid in some palatable form.

Recurring Pleural Empyema.—J. H. Pryor gives full details of one case, his patient being a young man, nineteen and a half years old. In 1904 he had pneumonia followed by empyema and the usual rib resection was done. He remained in the best of health for nearly three years, when he began to have a harassing cough, fever, and progressive weakness. Examination showed nothing to account for his symptoms, but in the course of two months it was pretty evident that there was pus in the chest somewhere on the side previously affected, and a second operation revealed a pus sac. The patient fully recovered after a prolonged convalescence. Pryor states that recurring empyema is an extremely rare affection, this being the third case on record, on the basis of an extremely careful search of the literature of empyema, both medical and surgical. Secondary attacks are apt to assume the sacculated or localized form, on account of the pathological changes following a preceding general involvement of a large part of the pleura. The symptoms are confusing, and may be ascribed to tuberculosis. Some time may be required to form an opinion by exclusion. It is conjectured that microbe life may remain latent in a pocket formed in the process of healing after the primary attack and again become active under unknown favorable conditions. In the foregoing case, there was no record of the bacteriological content of the pus removed in the primary operation, performed before the patient came under the author's care. Streptococci were found the second time. Whether the time of closure of the external opening has any relation to recurrence is an unsettled point.

Journal of the American Medical Association, December 28, 1907.

Diverticulum of the Vermiform Appendix.—Isabella C. Herb reports a case of appendicular diverticulum, probably owing its origin to an attack of appendicitis sixteen years prior to its discovery. The appendix was enlarged

and occluded and the diverticulum sprang from its middle portion opposite the mesenteric attachment, in the form of a globular mass nine inches in circumference and containing opaque jelly-like contents. The reasons for considering the cyst to be a diverticulum rather than a dermoid, hydatid or implantation, cyst, etc., are given. The author has found in the literature twenty-four other cases of diverticula of the appendix.

Pathology and Therapeutics.—G. F. Butler points out the errors that result from the prevalent conception of pathology as being simply pathological anatomy. Pathological anatomy deals with the destruction of physiological structure produced by disease, rather than the disorders of biochemistry and physiology produced by any factor that disturbs the previously existing physiological balance of the organism. It is in the treatment of the perversions of physiological function rather than in the treatment of the diseased anatomic conditions that therapy has achieved its great and lasting successes. He illustrates his view by the therapeutic indications for the improvement of the renal, hepatic, and adrenal functions in epilepsy and hysteria instead of merely attempting to suppress the convulsive manifestations, and the pathophysiological phenomena in diabetes, nephritis, etc., which call for therapeutic measures rather than the specific lesions themselves. It is the pathophysiology of the disease that needs attention rather than the nosological label, and more even than the patient himself, otherwise than as viewed from this physiological standpoint.

Phlegmonous Gastritis.—H. E. Robertson reports two cases of this disorder, in both of which streptococci were found in the lesions, and briefly reviews the literature. The etiology, clinical symptoms, diagnosis and treatment, pathology and bacteriology are also discussed and the article is summarized substantially as follows: 1. Phlegmonous gastritis is a rare form of gastric inflammation characterized by diffuse or focal infiltration of the stomach walls by pus and serum. 2. It is due to the entrance into the submucosa of a virulent organism, usually the streptococcus, through some lesion, though in some cases this has not been discovered. 3. It is more common in males of alcoholic habits and at or past middle life. 4. The clinical symptoms are vomiting, thirst, pain and tenderness in the epigastrium, fever, rapid pulse, signs of peritonitis, collapse, and sudden death. 5. Its duration ranges from twenty-four hours to fourteen days, averaging from four to six days. Diagnosis is usually made at autopsy. 6. The prognosis is very grave and treatment, beyond relieving pain, of no avail. 7. The autopsy frequently shows, in addition to the stomach lesions, a purulent peritonitis and associated lesions. 8. Bacteriologic examination usually yields the streptococcus in pure culture. The circumscribed forms of the disease with focal abscesses are, in Robertson's opinion, probably due to a mixed infection or by some other organism, such as the staphylococcus.

Intrapulmonary (Intracavital) Injections.—M. R. Smirnow reports two cases of extensive and otherwise uncontrollable pulmonary hemorrhage in tuberculosis, successfully treated by the injection under antiseptic precautions, of 5 grains of tannic acid dissolved in 5 c.c. of water, directly into the blood-filled cavity in the lung. In one of the patients this was done on two separate occasions, months apart. In every trial of the method it was quickly effective in checking the hemorrhage and relieving the patient. He recommends the procedure to the profession in the following conditions: 1. The hemorrhage must be in a cavity and uncontrollable. 2. It must be definitely located. 3. Judgment as to the size of the cavity and its location and depth from the chest wall must be as accurate as possible, and the best results are obtained when the needle enters directly into the cavity. 4. The danger of infection is great, and, therefore, the most stringent aseptic precautions must be employed. 5. Tannic acid, or any other soluble unirritating substance that will readily form a clot, may be employed. 6. The low condition of the patient is not contraindicatory, as the injection is a last resort.

The Lancet, December 16, 1907.

Extensive Surgical Emphysema.—G. B. Buchanan's patient was a man of 66 years, who fell, striking his chest against the corner of a table and fracturing the seventh and eighth ribs on the left side rather towards the back. About three hours afterwards he noticed that his scrotum was becoming swollen and uncomfortable and this swelling advanced rapidly over the whole body. Twenty-four hours after the injury the body was found to be swollen and puffy all over and the air could be felt crackling under the fingers; it was evidently immediately beneath the skin, which was lifted up in a large soft mass producing the appearance of general dropsy. The entire surface of the body was affected with the following exceptions: the scalp, defined by a line running round the head more or less coronally at the level of the external occipital protuberance, the temporal ridge, and the upper and outer angle of the orbit, and this area of immunity was continued downwards to the malar bones, and thence over the nose as far down as the tip, the eyes and eyelids thus escaping; the point of the chin; the auricles; the hands, back and front, from a line just above the wrist-joint; the region immediately over the patella; and the feet, dorsum, and sole from a line at the ankle-joint. There was no sign of pneumothorax. For the first day or two there was a little dyspnea, with slight cyanosis of the face and lips, and rather rapid respiration, but this soon passed off. There was no pain anywhere except at the site of the fracture, though the swelling of the scrotum and penis gave rise to considerable discomfort. Treatment consisted in restricting the movements of the chest by strapping and the administration of sedatives for the cough. The emphysema gradually subsided and in a fortnight it had quite disappeared. Noteworthy features of the case were the immunity of the areas over the nose and eyelids, as there is a free communication between the subcutaneous tissues of these parts; also the definite limiting line at the wrists.

The Synchronous Movements of the Lower Eyelids with the Tongue and Lower Jaw, Observed in Certain Diseases.—The movements referred to by H. J. Bobson consist of a slight eversion of the lower eyelids, made evident on the protrusion of the tongue or depression of the lower jaw, the lids resuming their normal state when the tongue is retracted or the mouth shut; in other words, the lower lids become displaced from the eyeballs or are protruded from the eyeballs to the extent of one or two millimeters upon protrusion of the tongue or depression of the lower jaw. The author does not think that the phenomenon is a reflex act of disease. It is evidently produced by the contraction of the malaris fibers of the orbicularis palpebrarum muscle—the malaris muscle as described by Henle. From the fact that the facial nerve supplies the malaris muscle and the digastric and mylohyoid muscles, and the hypoglossal nerve supplies the geniohyoid and the geniohyoglossus muscles, and that the facial nerve communicates in the latter muscle with the hypoglossal nerve; and furthermore, from the fact that the nuclei of origin of the hypoglossal nerve and of the facial nerve are in close proximity in the medulla and the pons varolii, respectively, it is easy to see how the coordinate muscular acts of the simultaneous protrusion of the tongue and depression of the lower jaw with the eversion of the lower eyelids are produced. In acute cases Bobson is inclined to think that the presence of the sign may be caused by the circulation in the blood of some toxin, or that at other times it may be some nervous impulse acting directly upon the common nuclei of origin of the hypoglossal nerve and of those fibers of the facial nerve supplying the orbicularis palpebrarum and its offshoot, the malaris muscle. In chronic cases it is obviously caused by some changes in the deeper structures of the skin. It has been observed in acute influenza laryngitis and in chronic maladies of the heart and abdominal viscera. The author declares that the phenomenon is never present in health, but comes and goes with the onset and cure of the disease, of which he thinks it is a clear index or sign.

Some Gastric Conditions in Wasted Infants.—R. Miller and W. H. Willcox make a plea for examining gastric contents in wasting infants. They refer particularly to results in atrophic dyspepsia and hypertrophic pyloric stenosis and acid dyspepsia. The first group shows a diminished activity of both acid and ferment secreting glands. There is no retention of food in the stomach and there is no mucin. In the second class there is, as a rule, a marked increase in the ferment activity, together with excessive secretion of mucin. There is also found to be very obvious retention of food in the stomach. The total acidity is variable, but tends to be below normal, varying doubtless indirectly with the amount of gastritis present. It may be pointed out that after regular gastric lavage has been carried out for a short period the gastric contents begin to lose their abnormalities—the mucin becoming less in amount, the ferment activity diminishing, and the acidity at the same time more closely approaching the normal. In the third variety the gastric contents show an increase in their total acidity, the ferment activity being normal or below normal. There is no mucin, but there is obvious retention of food in the stomach. The clinical symptoms of the various conditions are fully described, together with treatment.

British Medical Journal, December 14, 1907.

Ptomaine Poisoning from Mutton with Marked Bradycardia.—The patient of W. Bryson was a farmer of thirty-nine years, whose symptoms began some three hours after he had eaten the mutton, the weather being warm and sultry but the meat being all right so far as its appearance was concerned. Several others who had partaken of the same meat were attacked, though less violently. The symptoms were the usual ones of gastro-enteric irritation, vomiting, diarrhea, tympanites, and some abdominal tenderness. Later cramps in the extremities were added. The pulse ran down to 48 and was regular. The breath had a peculiar fetid odor. The symptoms lasted in all over five days and recovery ensued.

Treatment of Scabies.—F. J. W. Porter commends the use of balsam of Peru, followed by a hot bath in twenty-four hours. Out of twenty-four cases this proved efficient, no case relapsing and no albumin being found in the urine. Some figures are given as to the frequency of the disease in the English army.

A Note on Nephropexy.—B. Pollard refers to an operation which he has satisfactorily performed, the principle being the support of the kidney by means of a sling fashioned from a part of its own capsule, additional support being ultimately obtained by the union of the decapsulated surface of the kidney with the posterior wall of the abdomen. Full technical details are given in the original paper.

The Part Played by the Pediculus Corporis in the Transmission of Relapsing Fever.—J. P. Mackie gives a general description of the pediculus and then describes a certain epidemic in which it appeared to play a causative factor. The features of this epidemic are thus summarized: (1) An epidemic of relapsing fever broke out in a mixed settlement of boys and girls living under similar conditions. (2) A very high percentage of the boys fell victims to the disease in the course of a few weeks. (3) A much smaller percentage of girls fell ill and at infrequent intervals extending over three months. (4) The most notable factor in which the boys differed from the girls was that they were infested with body lice, from which parasite the girls were almost free. (5) A well-marked percentage of the lice taken from the infected ward contained living and multiplying spirilla. (6) The stomach of the louse was the chief seat of multiplication, and this was carried on in the face of active digestion and after the disappearance of all other cellular elements. Other organs became secondarily infected. The secretion expressed from the mouth of infected lice contained numbers of living spirilla, and they also existed in greater or less numbers in the upper alimentary tract. The ovary was frequently infected, but spirilla were not found in deposited ova. (7) With the increase of the epidemic amongst the girls, body lice became more in evidence. (8) With the subsidence of the epidemic amongst the boys, the percentage of infected lice fell. (9) An attempt to infect a monkey by means of lice failed.

A Possible Explanation of Late Return Cases of Scarlet Fever.—W. Habgood notes that every physician responsible for the discharge of scarlet fever patients from isolation hospitals is beset with the difficulty of knowing when they are free from infection. The time having not yet arrived when he can, as in the case of diphtheria, call in the aid of the bacteriologist, he has to be guided by ordinary clinical examination. Formerly desquamation was the guide; when that was completed the case was discharged. Of recent years it has been recognized that where return cases of scarlet fever occur the discharged patient will be found to have some purulent or mucopurulent discharge. While admitting the impossibility of being sure that all inflammation has ceased in the upper respiratory tract, the author is inclined to believe, from observation at different hospitals in the last two years, that cases are sent out free from any nasal discharge and not infectious, but do again become infectious by the occurrence of an ordinary attack of nasal catarrh, which causes some remaining quiescent scarlet fever germs to renew their activity. An anology may be found in the case of one who sits in a warm room with a current of cold air playing on his neck. He may get an attack of acute nasal catarrh, and he may become infectious to others. The germs that caused the catarrh were already in his nose, but dormant and able to become active only when an interference with the nasal circulation was set up by the cold air driving on to the warm skin. Habgood thinks it may be argued that the scarlet fever convalescent causing a "return case" has in some instances left the house, not in an infectious state, but owing to the change from a healthy, open-air life and freely ventilated wards of a hospital to the stuffy and ill ventilated rooms of a cottage he has become more than usually liable to nasal catarrh—has, indeed, suffered from such an attack and is thereby again made capable of conveying scarlet fever infection.

Berliner klinische Wochenschrift, December 2 *and* 9, 1907.

The Hydrochloric Acid Treatment of Gout.—Falkenstein reports on the results of five years' application of his hydrochloric acid therapy in gout. This is founded on his belief that in gout there is a hereditary abnormality of the gastric mucosa involving the fundus glands and causing diminished hydrochloric acid secretion. The method consists in the continuous administration of considerable quantities of concentrated pure hydrochloric acid, which is given well diluted after meals. The author himself has taken during more than five years without any interruption 50 to 60 drops daily of the concentrated acid without any untoward effects, and with very great relief to his gouty symptoms. He has treated 390 cases of the disease and says that the patients may be divided into three groups. The first category comprises patients who have had the disease for only a few years and who accordingly have only moderate uratic deposits. With these the hydrochloric acid treament is usually very effective and a permanent cure is possible. The second class includes cases of chronic typical or irregular gout in which in the course of years very considerable deposits and tophi have formed. These patients also experience great improvement in the general condition and cessation in the progress of the disease. Further attacks are not altogether prevented, but are usually not severe. The acid is effective only in preventing new deposits and does not cause solution of those already present. In the third group he places the severest cases of chronic gout, and patients of this type apparently benefit but little by the use of the acid. The author also recommends the addition of from 2 to 400 grams of crude hydrochloric acid to a bath tub full of warm water as an efficient means of promoting cutaneous activity in gouty patients. The patients should stay in the bath about ten minutes and repeat it at intervals of one or two weeks.

Dysentery Due to Ciliates.—Rheindorf describes the conditions present in six specimens of large intestine obtained from patients dying of dysentery in the Russian-Japanese war. In these there were found large numbers of organisms which could be identified as ciliates, probably the *Balantidium coli*. There has been doubt in previous instances as to the rôle played by the organism in causing the symptoms, some authors have denied the pathogenicity of the animalcule, but the majority consider it as the etiological factor of this form of colitis. Rheindorf is of the same opinion and states that in microscopic sections the parasites could be found far below the surface of the intestine and unaccompanied by the bacteria. The mucous membrane showed areas of necrosis and ulcers with undermined edges extending to the muscular layer. In some instances there was a considerable inflammatory reaction and in places there was pronounced edema of the submucosa. The parasites were from 50 to 80 microns in diameter and were most numerous in the submucosa at the edges of the ulcers. About 100 cases have been reported with 20 deaths; most of these have been in Russia and Scandinavia. The infection is thought to take place from the pig, which nearly always harbors the parasites in its intestine.

Thyroid Disturbance Caused by Iodine Intoxication.—Warschauer reports an unusual instance of intoxication apparently induced by potassium iodide. The patient was a woman 28 years of age who came under another physician's care on account of a chronic eczema of one leg. This was considered as being syphilitic in nature and inunctions of blue ointment and potassium iodide were administered off and on during four weeks. The patient then began to suffer from great weakness and an erythema appeared over the entire body, the face became edematous, there was loss of appetite, violent diarrhea, subnormal temperature, and a pulse of 100-120. At this time she came under the author's observation and the potassium iodide was stopped and the diarrhea checked with opium. The condition continued to grow worse, however; the skin became very dry and scaly, the hair fell out, the emaciation became extreme, the loss of weight amounting to sixty pounds in seven weeks, and a consultant made the diagnosis of Addison's disease. The pulse could not be counted, at times there was delirium, bed sores appeared, and the urine became albuminous. Earlier in the illness the administration of thyroid tablets had been tried, but had been given up again owing to cardiac distress. Now, as a last resort, this remedy was again resorted to, later

on supplemented by sodium phosphate. At the end of eight days the improvement was very perceptible and at the end of about four months the patient's condition was practically normal in all respects. The author regards the case as an instance of thyroid disturbance due to intoxication by potassium iodide.

Münchener medizinische Wochenschrift, December 3 and 10, 1907.

The Minimum Albumin Requisite.—Forster, in discussing the subject of nutrition, says that it is coming to be realized that there is a danger in reducing the albumin intake to the minimum at which nitrogen balance can be maintained. In addition to albumin, fat, and carbohydrates the human body requires for the growth and maintenance of its organs a sufficiency of other substances such as the inorganic salts. In food stuffs these are found in combination with albuminous bodies or in close relation with these, so that if the amount of proteid ingested is greatly reduced there is also risk of impairing nutrition through deficiency in salts. Furthermore, the breaking up of albumin in the body results in the formation of certain essential substances such as the digestive ferments, protective bodies, internal secretions, etc. It has been proved for some of these, and it is probable for the others, that their production is in proportion to the splitting of albumin in the body, and it is therefore to be expected that with low albumin metabolism disturbances in health may result from deficiency in such bodies. Until the conditions underlying both of these processes have been more fully elucidated it is desirable from the standpoint of general physiology and hygiene to maintain an active proteid metabolism and not to reduce the albuminous food stuffs too low.

Three Thousand Ethyl Chloride Narcoses.—Herrenknecht, who has conducted three thousand anesthesias with ethyl chloride without any mishap, considers that when carefully used by those experienced in its administration it is the safest anesthetic at our disposal, not excepting laughing gas. In five cases of the series anesthesia could not be induced owing to the great restlessness of the patients while in the first stage of excitement. The action of the anesthetic may be divided into four stages: First, the prenarcotic analgesic stage; second, the stage of excitement; third, the stage of deep sleep, and four, the postnarcotic analgesic stage. If the patient shows signs of awakening before the surgical procedure has been finished, a second anesthesia may immediately be begun, but in general for operations that are likely to consume more than five minutes it is preferable to begin with ethylchloride and continue with ether or chloroform. Operations requiring only a half to one minute may be performed in the prenarcotic stage. During this the patient is conscious, but has little or no sensibility to pain. Healthy persons are able to walk home alone immediately after the operation. An important observation is that during the anesthesia erotic delusions are often present, so that especially in dealing with women it is desirable to have witnesses at hand. The author uses an Esmarch chloroform mask with an impermeable covering leaving an empty space between the covering and the flannel. A small circular opening is cut in the covering and through this the anesthetic is sprayed on the flannel. The edge of the rubber covering extends beyond the mask, so that it may be closely adapted to the features of the patient by the fingers of an assistant. Ordinarily 2-3 g. of ethyl chloride are sufficient to produce anesthesia, 5 g. being but rarely necessary.

A Case of Swine Erysipelas in Man Cured by the Use of Serum.—Welzel says that several cases have been reported in which human beings, usually veterinarians, have been infected with the bacilli of swine erysipelas. In performing the immunizations which are now done on a large scale, the antiserum is injected into the animal and also a very small amount of a pure culture of the bacilli. In doing this it not infrequently happens that the operator pricks or scratches himself, owing to the restlessness of the animal. Of five cases of this sort reported one ended fatally and the ordinary surgical measures applied did not appear to modify the course of the disease in the others. Another veterinarian who accidentally inoculated himself promptly injected some of the immune serum, with the result that the symptoms quickly subsided. Welzel's own patient was a veterinarian who inoculated himself in the course of his work and manifested symptoms of a severe infection that threatened to become generalized. A single injection of the ordinary immune serum used for treating pigs sufficed to arrest the infection and produced almost instant relief in regard to both the pain and the local symptoms.

Renal Decapsulation in Eclampsia.—Franck summarizes the histories of nine cases in which Edebohl's suggestion of renal decapsulation for the treatment of eclampsia has been carried out and adds the description of a tenth case of his own. In this instance the patient, who had passed into the status eclampticus and had seizures every ten minutes, did not improve after accouchement forcé and fifteen hours later was practically moribund, with suppression of urine. Double decapsulation was done without anesthesia and a diminution in the attacks very promptly resulted, so that during the succeeding twenty-four hours there were very few and twenty-four hours after the operation they ceased entirely, the patient became conscious, and a considerable amount of urine with only a comparatively moderate albumin content was voided. The improvement in the patient's condition was striking, but she died as the result of a bronchopneumonia on the fourth day. The author considers that while the mortality of the reported cases is about 30 per cent., this is in large measure due to the fact that most of the patients were already in desperate straits, and he believes that in cases in which the seizures persist after the uterus has been emptied, decapsulation should immediately be resorted to.

Employment of Adrenal Extract in Spinal Anesthesia. Michelsson is of the opinion that the addition of adrenal extract to the anesthetic injected in inducing spinal anesthesia is not only useless but even undesirable, and believes that some of the disagreeable sequelæ of the procedure as ordinarily carried out may be referable to this factor. The first impetus to the use of adrenalin for this purpose was given by the work of Dönitz, who found on experimenting with cats that the animals withstood a larger amount of cocaine injected intraspinally if adrenalin was present than if this was omitted. He adopted as a control the figures given by Eden, who gave cocaine alone, but he did not take into account the comparative weights of the animals used in the two sets of experiments, and Michelsson has found that actually the fatal dose per kilogram was practically the same whether adrenalin was used or not. Michelsson's own experience has been that patients anesthetized without the use of suprarenal gland preparations suffer less from headache, backache, etc., than when the drug is used.

French and Italian Journals.

Tubercle Bacilli Entering by Way of the Intact Skin.—V. Babès has shown that the tubercle bacillus may enter the body through the unbroken skin, and that this may happen especially in the infant on account of its more tender skin. The entrance of the bacteria is favored by washing and shaving the skin, and a certain amount of dirt and scales upon the skin act as a protector against their entrance. The germs pass directly to the nearest lymphatic glands. Slight skin lesions in children and eczema favor the entrance of the bacilli. Tuberculosis which has thus reached the glands progresses very slowly and is often found in the glands of the mediastinum and the bronchial glands at autopsy, without having given any signs during life. Such children are called scrofulous.—*La Presse Médicale*, June 15, 1907.

Acute Pulmonary Edema.—H. Mery and L. Badonneix say that acute pulmonary edema is always an active process resulting from a sudden elevation of arterial tension in the pulmonary artery and characterized by a sudden effusion of serum into the alveoli. It is distinguished from passive congestion by the suddenness of its onset and the severity of its results. It is essentially noninflammatory. It results from affections of the kidneys, and of the aorta, in gouty subjects, and in rheumatic conditions, as well as in some forms of intoxication. There is present arterial edema, and an afflux of blood favored by vasodilatation of the arterial system. Various theories are advanced as to its causation; the angioneurotic and toxic are the principal ones. The lungs are rigid, turgescent, and erectile. There is intraalveolar edema, the alveoli being distended with an albuminous fluid without fibrin. Symptoms are urgent dyspnea, respiratory anguish, and pressure of crepitant and bubbling râles. There is no modification of the respiratory rhythm, and no elevation of the temperature is observed. Death occurs rapidly, often after more or less severe convulsions. The treatment of the condition is mainly prophylactic. Sparteine and strophanthus are often of considerable value, but the authors say that the use of digitalis is strongly contraindicated. Morphine is never admissible. Oxygen inhalations will sometimes be found to be of real service.—*Gazette des Hôpitaux*, September 26, 1907.

Book Reviews.

The Practice of Obstetrics by American Authors. Edited by Charles Jewett, M.D., Professor of Obstetrics and Gynecology in the Long Island College Hospital, New York. Third Edition, Revised and Enlarged. Illustrated with 484 Engravings, 46 of which are in Colors, and 36 Colored Plates. New York and Philadelphia: Lea Brothers & Co., 1907.

The third edition of this work is very little larger than the previous one; but six of the thirty-four chapters are by new writers. We miss the contributions of Drs. Palmer, Crockett, and Chapin, just as in the former edition we did those of Drs. Browning, Davis, and Etheridge which appeared in the original work. The first chapter, on anatomy, still remains one of the best on the subject. The third chapter, on changes in the maternal organism caused by pregnancy, is a new one and is written by Dr. W. S. Stone; the chief feature of it is a section on the normal metabolism of pregnancy and a page of bibliography (almost exclusively German). The chapters on duration of pregnancy and on hygiene and management of pregnancy are also by Dr. Stone; in the former chapter we miss the section on evidence of former pregnancy; the bibliography (as above) is present. The chapter on toxemia of pregnancy is by the same writer, and is, we think, the best of his contributions. Dr. Bartley contributes the chapter on malformations, injuries, and diseases of the newborn child, but much of it is couched in the same words as were used by Chapin in the previous edition. The book, like all works of composite authorship, contains chapters of very unequal merit. The sections on anatomy, the management of normal labor, eclampsia, and puerperal infection are models of what such work should be. As a whole, the book is exceedingly useful; the illustrations are particularly good, and the shortcomings are few and insignificant beside the many sterling qualities it possesses.

Clinical Therapeutics. A Handbook on the Special Treatment of Internal Diseases. By Alfred C. Croftan. Second Edition, Revised. Chicago: Cleveland Press, 1907.

That a second edition of this work has been demanded within a year speaks well for its popularity. After a careful perusal the reason is not hard to find, for the author has supplied that which is so often lacking in works on materia medica. A knowledge of the physiological action of drugs is properly presupposed and the text deals more with their application and indications. But above all we note the careful attention to the details of methods other than that of administering drugs. Physical therapeutics here have a champion who has used them and is a strong advocate of them. Hydrotherapy is especially prominent, and his technique is excellent and carefully given, including the temperature, duration, and manner of application. Rest, exercise, climate, and many of the smaller comforts such as serve to stem the ravages of disease are fully and rationally presented. The work is extremely interesting, helpful, and readable. Indications are given alongside the contraindications and the reader feels that he is dealing with sick humanity and not with laboratory animals. It is without doubt one of the best expositions of clinical therapeutics that we have seen. Some of the newest and insufficiently tried methods the author has purposely omitted, since they have not yet found their proof or place. This edition does not differ much from the first, except that it has been thoroughly revised.

The Principles and Practice of Modern Surgery. By Roswell Park, A.M., M.D., LL.D. (Yale); Professor of the Principles and Practice of Surgery and of Clinical Surgery in the Medical Department of the University of Buffalo, N. Y.; Member of the German, Italian, and French Surgical Societies; Ex-President of the American Surgical Association and of the Medical Society of the State of New York; Surgeon to the Buffalo General Hospital, etc. Illustrated. Philadelphia and New York: Lea Brothers & Co., 1907.

This individual work succeeds the Treatise on Surgery by American Authors, the third edition of which has just been exhausted. The material and illustrations in that treatise have been freely used in this new volume. The object of this present volume, the author states, is to place the subject before students and practitioners in a way to instruct from the beginning through to the operative and post-operative treatment. Obsolete and obsolescent material has therefore been excluded and the pages are devoted to present-day principles and practice, stated as clearly and succinctly as possible. Illustrations have been freely employed wherever a point could be so explained to the eye. A chapter of special value is the one bearing on tumors, in the preparation of which he is indebted to Dr. H. R. Gaylor, who has contributed certain material. Tumors are classified and considered as follows: (1) Cysts, (2) dermoids, (3) teratomas, (4) tumors of connective-tissue type, (5) tumors of nerve elements, (6) tumors derived from epithelium. The author does not feel justified in lauding too highly the newly introduced system of opsonic therapy and holds that suspension of judgment is demanded until more extensive trial is made of it. In considering the treatment of tuberculous arthritis he states that the fundamental idea expressed in all of the methods for enforcing rest by traction is of American origin, and constitutes one of the advances in surgery for which the world is indebted to America. For a long time it was referred to in Germany as the American method, and yet now the Germans claim so much for it that one of their surgeons has written a book of 600 pages devoted to the employment of traction for various surgical purposes, in which but little credit is given to the men who originated it. Of special interest is the chapter on the abdomen and abdominal viscera. One hears to-day of many insisting that the abdomen is too often opened; Dr. Park believes it would be more just to say that it is opened by too many. The book as a whole is one that is in every way an exposition of the present state of surgery and must take its place as an authority.

A Text-book of Physiological Chemistry. For Students of Medicine and Physicians. By Charles E. Simon, B.A., M.D., Professor of Clinical Pathology at the Baltimore Medical College. Third Edition, Thoroughly Revised. Philadelphia and New Lork: Lea Brothers & Company, 1907.

In its general arrangement this admirable work remains unchanged, but inspection of the several sections shows that it has undergone careful revision. This is particularly apparent in the first two chapters and in those on the ferments and on the urine, which are fully representative of the many advances that have been made during the past year or two in these departments of physiological chemistry. Most of those interested in this subject are already familiar with Professor Simon's authoritative text-book and those who are not may be strongly urged to remedy what is a real deficiency.

Text-book of Diseases of the Skin. By Arthur Van Harlingen, Ph.B. (Yale), M.D., Emeritus Professor of Dermatology in the Philadelphia Polyclinic, Dermatologist to the Children's Hospital, Fellow of the College of Physicians of Philadelphia, Member of the American Medical Asociation. Fourth Edition, Thoroughly Revised and Rearranged, with 102 Illustrations. Philadelphia: P. Blakiston's Son & Co., 1907.

This book differs from previous editions of the work in the arrangement of the description of the various diseases. Instead of being entered alphabetically, as before, these are now arranged according to the classification generally adopted by American teachers, thus making it more useful to the student. After considering the anatomy and physiology of the skin and symptomatology, he treats diseases of the skin according to the following classification: Class I., Hyperemias. Class II., Inflammations. Class III., Hemorrhages. Class IV., Hypertrophies. Class V., Atrophies. Class VI., New Growths. Class VII., Neuroses. Class VIII., Diseases of the Appendages: (1) the nails, (2) the hair and hair follicles, (3) the sebaceous glands, (4) the sweat glands. Class IX., Parasitic Affections: (1) diseases due to vegetable parasites, (2) diseases due to animal parasites. This classification is the one based upon that of Hebra and upon a nomenclature sanctioned by the American Dermatological Association. By its general adoption students all over the country are being taught on the same general scheme. Much of the "confusion of tongues" has arisen from the effort on the part of each writer to put forth such a classification and nomenclature as seemed most perfect, but with little regard to the arrangement of others.

Report on the Advancement of Pharmaceutical Chemistry and Therapeutics. Volume XX., 1906. Darmstadt: E. Merck & Co., 1907.

This annual contains detailed descriptions of the new drugs and new uses of old drugs compiled from the literature of 1906. It will be found useful as a work of reference, containing, as it does, information regarding many of the most recent synthetics and other drugs of German preparation.

Society Reports.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, Held November 18, 1907.

THE PRESIDENT, DR. THOMAS E. SATTERTHWAITE, IN THE CHAIR.

Some New Points in the Treatment of Excessive Gastric Secretion.—Dr. L. KAST read this paper.

Report of the Committee on the Death of Dr. Richard H. Derby.—The Chairman, Dr. C. COLE BRADLEY, read this report.

Report of the Committee on the Death of Dr. Francis H. Markoe.—The Chairman, Dr. FRANCIS P. KINNICUTT, read this report.

Gallstone Disease in Its Surgical Aspect.—Dr. FORBES HAWKES said that when a positive diagnosis of gallstones had been made in a given case, the question arose, did the condition belong among those to be treated by medical means or by surgical ones? If we excluded those cases (and he was not at all sure that even those should be excluded) in which gallstones were being constantly passed with slight discomfort to the patient, and those in which the risk of any surgical procedure was very great from cardiac, pulmonary, renal, or arterial changes, or from a marked hyperadiposity, the speaker thought he was voicing the opinion of many conservative surgeons to-day when he said that the remaining conditions might best be treated by surgical methods. Gallstone surgery had been and was still being opposed by many medical men in much the same way that the surgery of the appendix was opposed. Gallstone patients were liable at any time to the following serious complications: (1) Abscess of the gall-bladder, often with subphrenic abscess secondary to it; (2) gangrene of the gall-bladder, with ensuing spreading peritonitis; (3) perforation of the gall-bladder into the duodenum, stomach, or transverse colon, with occasional intestinal obstruction from the contents or from subsequent constriction bands; (4) impaction of one or more of the calculi in the common or hepatic duct, followed by obstructive jaundice and later by ascending infection along the liver ducts, resulting in abscess of the liver, localized and operable, or diffuse and beyond the reach of the surgeon; (5) chronic hepatitis and chronic pancreatitis; (6) cancer developing in the vicinity of the gallstones. Before surgeons could conscientiously recommend operation as a routine measure with gallstones, they had to show that the operation *per se* was not an extra-hazardous one and that their final results were better in the cases operated on than in those treated by medical means alone. This had now been done by many surgeons the world over, and gallstones were being recognized more and more as objects which the surgeon was called upon to remove.

Diseases of the Liver Amenable to Surgical Treatment.—Dr. CLARENCE A. MCWILLIAMS, in this paper, briefly considered some surgical aspects of liver diseases, the indications for operative procedures, and the results. Much of it was borderline surgery, the boundaries of which had not as yet been clearly defined. To accomplish this a sympathetic attitude between the physician and surgeon must be maintained, each realizing his own limitations and the others' good intentions. The first condition discussed by the author was cirrhosis of the liver, in which statistics showed that surgical measures sufficed to relieve from 30 to 40 per cent. of patients affected with this disease of their ascites. Notwithstanding this fact, surgeons in general saw very few cases of ascites. The heavy mortality of about 20 to 30 per cent. in the past probably explained the reluctance of the physician to resort to surgical procedures, which might also possibly be accentuated by ignorance of the good results thus obtained. This mortality would be much reduced when the patients were operated on as soon as the ascites first developed, before the liver cells were too extensively degenerated and before the patients were too enfeebled by malnutrition. It was no fair test of the operation when it was performed as a last desperate chance. The operation was contraindicated when the patient was enfeebled by disease of the heart and of the kidneys, and when the liver had contracted to the extent of producing urobilinuria and acholia and hypocholia of the feces. Very successful results had also been obtained by performing the operation of drainage of the biliary passages (cholecystostomy) in the hypertrophic variety of cirrhosis of the liver, accompanied by icterus. According to Kocher, it would be the rule in all diseases of the liver accompanied by persistent jaundice, in which the latter was not clearly due to an inoperable disease, such as advanced liver and pancreatic cancer, to perform an exploratory laparotomy. In any such procedure, whatever be the ultimate cause, as was the case with calculus in the common duct, it went without saying that the operation should not be put off until the changes in the liver had gone on to such an advanced stage as to threaten the cholemic condition. In abscess of the liver the diagnosis in this climate was often rendered difficult by reason of the absence of any appreciable etiological factor. This was particularly true in the chronic cases, where there might be no fever present. In addition, the general leucocyte count might not be much elevated because of the lack of absorption through the thick walls of the abscess. Some cases, owing to the intermittent type of the fever, were usually mistaken for malaria; in other cases, typhoid fever was suspected. Malignant disease of the liver might also be mistaken for abscess of the liver. In many cases where there was doubt as to whether or not an abscess of the liver was present, the doubt must be cleared away by an exploratory puncture by means of a full-sized needle, always employing a general anesthetic, and with the strictest aseptic precautions. The existence of primary cancer of the liver was at one time denied, yet there could now be no doubt of its occurrence, as was proven by a number of published cases. In the early stage diagnosis was very difficult, and even when the abdomen was opened it might be perplexing to make an exact diagnosis of a malignant growth from gummata, simple tumors, etc. In partial or complete hepatoptosis the treatment in general consisted in the vast majority of cases in applying a well-fitting abdominal supporter of some kind.

Medical Treatment of Gallstone Disease.—Dr. REYNOLD WEBB WILCOX said that about eighteen months ago, when he read a paper on this subject before one of the national societies, one of the surgeons who participated in the discussion had expressed surprise that he had said anything about dissolving gallstones *in situ*. Still, one should not lose sight of the fact that this theory gained a firm foothold among the older writers, and that the use of Durande's mixture of turpentine and ether was sometimes followed by a cessation of symptoms for many years. The speaker said that the use of olive oil followed by high colonic irrigation with ice water had brought relief for long periods. While the number of cases thus relieved was comparatively small, we should bear in mind the fact that in from six to ten per cent. of all cadavers, gallstones were found, and that fully three-fourths of these were in persons over fifty years of age, and that of these not more than five per cent. of the cases in which gallstones were found gave any antecedent history of gallstone disease. Therefore the cessation of symptoms was not evidence that gallstones had been dissolved. The treatment of gallstones, Dr. Wilcox said,

was absolutely surgical, first, last, and always, but the treatment of gallstone disease had nothing whatever to do with surgery. The latter was the treatment of the condition of which gallstones were the final expression, and when the gallstones had been removed by surgical means, then came the treatment that would prevent the formation of more stones. There were two principal varieties of gallstones: (1) The calcium-bilirubin stones, which were formed in the biliary passages in the liver; (2) those of cholesterin, which were undoubtedly formed in the gall-bladder. That the calcium bilirubin calculi were formed in the liver ducts was proven (1) by the fact that after the gall-bladder and ducts had been cleaned out by a cholecystotomy, gallstones of this variety had continued to be passed through the biliary fistula; (2) that in abscess of the liver, gallstones of the calcium-bilirubin variety of such size had been found that they could only have been formed *in situ:* (3) that the Roentgen-ray plates of Dr. Carl Beck showed gallstones of the calcium-bilirubin variety in the liver itself; (4) the gall-bladder having been removed, attacks of biliary colic might continue. As to the modes of infection which gave rise to gallstones, we had (1) those from the intestinal canal, and (2) those from the portal vein, and the problem that we had to solve was to remove all conditions which caused a congestion of the portal system, and particularly those which favored systemic infection of the liver and produced stagnation of viscidity of the bile. The drugs that were indicated were those which caused elimination of the bile through the hepatic cells, and exerted a disinfectant action. Dr. Wilcox then gave a brief outline of his method of treatment in gallstone disease, together with an extensive dietary program. He emphasized the importance of frequent meals in order to secure a pretty free flow of bile. The main point in the medical treatment was to do everything possible to remove all sources of congestion and inflammation of the portal system, and this might be materially aided by massage and exercises, both resistive and mechanical.

Surgical Technique in Diseases of the Biliary Passages.—By Dr. JOHN F. ERDMANN. The author stated that in preparing a patient for any operation connected with the biliary passages he was accustomed to have the abdomen prepared high enough to encroach upon the extreme limits of the costal arch, and low enough to do an appendectomy, should occasion demand, through the usual site. The incision he practised was one through the right rectus muscle, either the outer and middle or the inner and middle third. The incision could be extended downward in a direct line. Free exposure of the cystic and common ducts was readily obtained by rotating the liver. This was done by extending the incision upwards, thereby encroaching upon the diaphragm to quite an extent or by the method of Bevan. Riedel's lobe should always be remembered, as it often resembled or might be mistaken for an inflamed and distended gall-bladder. In cases in which atrophy or apparent absence of the gall-bladder existed, it was advisable to find the main (cystic) fissure, and then trace downward and backward toward the transverse fissure. In these cases, the sandbag or rest, as used in duct work, with free upward extension of the incision in the abdominal wall so that rotation of the liver could readily be obtained, was also of great benefit. In all cases of pericholecystitis accompanying cholecystitis, the adhesions of the omentum, etc., should be carefully released. Gauze packing was then placed between the bladder and the released adhesions or viscera before further search was made. When this was done, search was made for stones in the bladder, cystic duct, and finally in the hepatic and common ducts. It was often impossible in a fully or overdistended gall-bladder that was thickened by either recurring attacks or by the single acute one to feel a stone or stones through the wall. The cystic duct might be hidden in its upper (bladder) portion by the elongation or overdistention of Hartman's pouch. The lower (common duct) portion and the common duct could usually be palpated when the foramen of Winslow was patent, although the speaker said he was never satisfied with palpation of the common duct in a jaundice case, or one recently jaundiced, until he had opened the duct and palpated its interior. This interior palpation should be done, as Mayo had so ably emphasized, with the finger and not with a probe, as stones were often passed by the probe that the finger would reveal. When the bladder was distended he incised the fundus, emptying the contents, and by so doing the pouch of Hartman collapsed, allowing free examination of the upper extremity of the cystic duct to be made. This was also a very decided point to bear in mind when doing a cholecystectomy, as in trying to remove the unemptied bladder, particularly in those who were fat, Hartman's pouch obscured the field of the cystic duct to such a degree as to render the operation not only difficult, but dangerous. Dr. Erdmann then described in detail his technique in performing cholecystotomy, cholecystectomy, and choledochotomy.

Dr. WILLIAM H. THOMSON said he did not know of any diagnostic problem which, on the whole, was so easily solved as a case of single uncomplicated gallstones. In addition to the clinical symptom of the sudden pain with its characteristic radiation, we had physical signs which were as distinctive as those of a calculus in the ureter. With the impaction of a gallstone in the cystic duct there was a point of tenderness which was quite as definite as McBurney's point in appendicitis, and which was located half an inch above and to the right of the umbilicus. In examining a patient for gallstones, he should be asked to sit on the edge of a chair and lean forward, in which posture the abdominal muscles were relaxed. With the examiner standing behind him, the patient should now be instructed to take a full breath, and then, upon expiration, the fingers could be passed underneath the gall-bladder. In obstruction of the common duct, the point of tenderness was at the arch of the false ribs, about two inches above the point of tenderness in cases of involvement of the cystic duct. Another symptom of gallstone colic was the characteristic rigidity of the abdominal muscles, and if the attacks were at all recurrent, we had unmistakable symptoms of a localized gastritis. Then, if there was a history of rigors and jaundice, no diagnosis could be plainer. Dr. Thomson said he protested against calling these biliary concretions stones: they were albuminous mostly in their composition and floated in water, and they were particularly soluble in normal bile before the latter had entered the gall-bladder. Normal bile, when obtained through a biliary fistula, exerted powerful soluble properties on gallstones, but after it entered the gall-bladder it began to be concentrated by absorption of its watery elements, so that its specific gravity rose from 1.010 to 1.030 or even 1.040. Dr. Thomson said the experience of the surgeon with gallstone cases was largely limited to the operating table. The number of cases of actual gallstones—not gallstone disease—was extremely large, and they came under the daily observation of the consultant. The speaker said that in cases in which there were no evidences of any suppurative process nor of any continued inflammatory process, he always advised giving medical treatment a thorough trial. He formerly prescribed ten grains each of sodium benzoate and sodium salicylate to be taken in vichy water an hour after each meal and at bedtime, but more recently he had favored the succinate of sodium, in five-grain doses, taken in the same way. At night he ordered two ounces of olive oil, taken in hot milk.

Dr. A. ERNEST GALLANT said that in his experience with cases of suspected gallstones the diagnosis had not been

as easy as Dr. Thomson's remarks would lead one to believe. He recalled a number of cases of the jaundice recurrent type which were regarded as due to gallstones or cancer of various intraabdominal organs, and in two recent cases so many diagnoses were offered by various consultants that an exploratory operation was done, and in both cases, upon opening the abdomen, the speaker said he found nothing but a movable kidney which was dragging on the common or cystic duct. This condition, the speaker thought, was comparatively frequent as a cause of supposed gallstone colic. His plan of clearing up the diagnosis was to raise the foot of the bed, allowing the patient to rest with the shoulders lower than the hips, and in that position the tension relieved and the pain would disappear. The condition could be permanently relieved by the application of a properly fitting abdominal "stock" binder, the use of plaster strapping, as suggested by Dr. Rose, or in women by wearing a specially designed corset.

Dr. Richard Ward Westbrook of Brooklyn said he failed to comprehend the line of distinction drawn by Dr. Wilcox between gallstone disease and gall-stones. Gallstones occurred as a result of various infections in the bile passages, and in their turn their presence assisted to renewed infection, from which arose symptoms known as gall-stone disease. There was no gallstone disease, as such, although there were well-recognized predisposing causes. The surgeon operated primarily not for the removal of the gall-stones, but for the purpose of draining the biliary tract, and when that was effectually done the infection was removed and there was no recurrence of the gallstones. About three years ago Dr. Mayo reported one thousand cases of gallstone operations without any recurrence where cholecystostomy had been done. In three or two instances where recurrence had taken place, small stones had been overlooked in the common duct. Dr. Westbrook said that gall-stones were formed primarily in the gall-bladder, secondarily in the ducts, and they did not form in the liver ducts to any such extent as Dr. Wilcox would have us suppose. This fact had been frequently confirmed on the operating table, and the *x*-ray plates of Dr. Carl Beck were not as convincing as were the statistics of Mayo and others. The medical treatment of gallstones, the speaker said, should be confined to the prophylactic aspect of the condition and the coexisting inflammatory or other complications. The actual cure of gallstone producing symptoms was surgical, and we could not divide these cases into those that could be cured, or "eliminated," medically as distinguished from those that could be cured surgically. There was no proof, the speaker said, that gallstones had ever been dissolved by medicinal substances taken by the mouth, although such stones may have been dissolved by injections through a sinus directly into the ducts. The operation for the removal of gallstones should be done thoroughly, as statistics showed that they did not recur with complete removal and proper drainage.

Dr. Achilles Rose said that he had had the privilege of listening to the lecture of Dr. Wm. H. Thomson on chololithiasis (not cholelithiasis as it is erroneously spelled by many) and that he remembered well how Dr. Thomson dwelt emphatically on the fact that formation of gallstones could only take place when infection as well as stagnation was present. Experiments on animals had proved that there could be no formation of gallstones without stagnation. Dr. Rose felt disappointed that the two speakers on therapy of gallstone disease, Dr. Hawkes and Dr. Wilcox had hardly considered this important fact, which should form the basis of prophylaxis and even of therapy, as the speaker had demonstrated in numerous writings, when he had shown that the relaxation of the abdominal muscles could be the cause of disorder of abdominal circulation in as far as the abdominal muscles controlled the distribution of the fluids in the abdomen, not only the blood but the water in the tissues and in the viscera—the secretions—among them the flow of bile. Relaxation of the abdominal muscles atonia gastrica, would certainly be apt to cause stagnation of bile. The speaker further said that frequently he had been able to convince himself that by properly supporting the relaxed abdominal muscles the circulatory equilibrium was restored, and that in case of gallstone colic the moving gallstones were set at rest, and pain was thus relieved. Dr. Rose said further that we could not dissolve gallstones by any medical treatment with which he was acquainted, but causing immobility of gallstones was good enough therapy in most cases. Among the medicines recommended salicylate of sodium appeared to him the most rational because it produced increased flow of bile which would have the effect of dislodging the wedged-in concrements and bringing them back into the gall-bladder or of eliminating them through the ducts, and also because this drug was, besides being cholagogue, an antiseptic and an analgesic.

Dr. Wm. Van Valzah Hayes said he had been able to demonstrate the value of the succinate of sodium in a number of cases of gallstone disease, and he now regarded it as his sheet anchor in the treatment of that condition. The only other remedy he had found to be of especial value was salicylic acid in combination with oleate of sodium and phenolphthalein (Bauermeister's formula). In the treatment of gallstone disease it was important to prevent irritation of the stomach and duodenum, as Dr. Wilcox suggested. A test meal should be given in these cases, and the functional condition of the stomach studied, so that any gastric abnormality that existed might be corrected. In certain cases surgical treatment was of course imperative.

Dr. Ransford E. Van Gieson of Brooklyn said there were some curious features connected with gallstone disease. One was that a person might have one attack of gallstones and never have another. He recalled a case that came under his observation thirty-five years ago in which the patient had a typical attack of gallstone colic with the subsequent discharge of the stone, and then had remained free from any recurrence for over thirty years, when he died of typhoid fever. Another interesting fact was that gallstones were frequently found post mortem in persons who had never complained of any symptoms pointing to gallstone disease. It was also a fact that cases of gallstone disease that were left alone or treated non-surgically showed a lower mortality than those that were operated upon. It should also be borne in mind that a thorough operation for gallstone disease was a very serious operation, and it should not be resorted to excepting in the face of one of two conditions, namely, infection or impaction. We might have to deal with obliterative inflammation of the gall-ducts without the presence of stones, and the speaker said he recently saw a case of that kind in which operation was performed against his advice, and which resulted fatally.

Dr. Wilcox, in closing, said there was no physical resemblance between the gallstones originating in the liver and those formed in the gall-bladder. When the gall-bladder was removed, of course that obviated the possibility of the formation of any more gallstones, if all gallstones originated in the gall-bladder.

Stated Meeting, Held December 16, 1907.

The Vice-President, Dr. Ransford E. Van Gieson, in the Chair.

Nomination for Officers.—The following officers were nominated for the ensuing year: *President*, Dr. Robert T. Morris; *Corresponding Secretary*, Dr. Frank C. Raynor of Brooklyn; *Treasurer*, Dr. A. Ernest Gallant;

Chairman for the Borough of Brooklyn, Dr. J. Scott Wood.

Report of the Committee on the Death of Dr. Seth D. Close.—By Dr. NATHAN B. VAN ETTEN, Chairman.

Changes in the Bile Occurring in Certain Infectious Diseases.—Dr. HELEN BALDWIN read a paper on this subject, in which she stated that the causes of gallstone formation were but little understood until about twenty years ago, when it was recognized by Budd, Bristowe, and Naunyn that most of the cholesterin in the bile was derived not from the blood, but from the degeneration of the epithelium lining the gall-bladder and the biliary passages, and that the formation of cholesterin gallstones was due to a local affection of these mucous membranes rather than to any constitutional disturbance. Dr. Baldwin said that during the winters of 1903 and 1904 she had had the opportunity of examining 225 specimens of bile which were obtained from autopsies from the City, Bellevue, Presbyterian, and Flood Wright Hospitals through the kindness of the pathologists in those laboratories. The work was done at the laboratory of Dr. C. A. Herter, under a grant from the Rockefeller Institute. By estimating the cholesterin and calcium present, and by studying the physical characteristics of the different specimens, an attempt was made to determine the relation between certain pathological conditions in the bile itself and the deposition of stones. In the routine examination of specimens of bile it was noteworthy that a large number were definitely abnormal. Of the 225 specimens examined, 72, or nearly one in three, showed definite morbid changes in the bile, although the symptoms were so slightly marked that a diagnosis of cholecystitis or of gallstone formation had been made in only two cases. In the series of cases noted 51 of the patients died of some infectious disease, and in 17, that is, one-third of these, there were characteristic changes in the bile which were not noted in patients dying from chronic diseases. With regard to the cholesterin content of the bile, the following facts were noted: That in an early stage of cholecystitis, where there was free drainage from the gall-bladder, and the epithelial cells were but slightly disintegrated, there was a slight increase in the cholesterin content of the bile. That where there was an obstruction to the flow of bile from the gall-bladder, and the bile was filled with masses of degenerating epithelium, there was a marked increase in the cholesterin. That where there was an excess of cholesterin in the contents of the gall-bladder, the most of this increase over the normal amount was held in suspension rather than in solution. Apart from these observations on the cholesterin in the bile, the most interesting fact noted was that cholecystitis in a mild or more marked degree was a common complication, not only of typhoid fever, as had been frequently observed, but also of pneumonia and of suppuration in other parts of the body. Usually this was so slight that it gave no distinctive symptoms, but a histological study of the wall of the gall-bladder showed the beginning of a chronic inflammation, and on examination of the bile there was found a marked desquamation of the epithelial cells of the mucous membrane. If the cystic duct was freely patulous these would be discharged into the intestine, but if there was a tendency to obstruction or if the desquamation of the epithelial cells was excessive, there would be a retention of degenerating epithelium elements in the gall-bladder, with the formation of cholesterin, or eventually the production of gallstones.

Dr. REYNOLD WEBB WILCOX said that Dr. Baldwin's paper was very interesting and furnished absolute proof of what clinicians had suspected for many years, namely, that gallstone formation in the gall-bladder was not the result of a local infection, but was due to a great variety of general infections, of which enteric fever was one and pneumonia was probably another, with the likelihood that several other infections would be proved to be also causative. The proofs sustaining this theory had never before been so well correlated as they had in Dr. Baldwin's paper to-night.

Dr. A. A. BERG said the results of Dr. Baldwin's investigations threw a great deal of light upon one of the functions of the liver, and the part this organ plays in infective diseases. The author of the paper had conclusively shown that the liver was a large excretory organ, and helped to eliminate bacteria both from the systemic and portal circulation. The speaker said that with this additional light thrown upon the infective character of the bile in cases of severe systemic and portal infection, we should be more favorably inclined toward relieving the liver by proper drainage of the bile, and when the symptoms indicated deep-seated septic involvement of the liver we should not hesitate to attempt to relieve the condition by proper drainage of the biliary apparatus through a cholecystostomy. He has had favorable results from such drainage in one case of systemic pneumococcus infection attended with cholecystitic manifestations, in one case of coli infection with similar gall-bladder inflammation. He regrets that in one case of systemic paracolon and typhoid infection, attended with gall bladder infection, he did not similarly drain the biliary passages, for he thinks the fatal issue might have been avoided by such procedure.

Blood Reactions of Inflammations.—Dr. E. E. SMITH read this paper, which will be published later.

Bacterial Vaccines and Curative Sera.—By Dr CHARLES F. BOLDUAN. (See page 6.)

Dr. N. B. POTTER said that Dr. Bolduan's paper contained a very able presentation of this subject, and he had only a few words to add regarding some practical experiences in the use of bacterial vaccines. Without entering into an extended review of different infections, he might say that the staphylococcus infections, particularly the more strictly localized ones like furuncles, acne, boils, and septic conditions were decidedly improved with appropriate doses of bacterial inoculations given at proper intervals. General diseases were apparently not helped as much by the inoculations as were the localized conditions. Nevertheless, the speaker said, he had seen a number of cases of generalized bacterial infection in which striking cures resulted and apparently from the use of the appropriate vaccines. Wright of London had published six cases of streptococcus infection in which the organisms were found in the circulating blood; of these six cases, three were cured after the use of the vaccine treatment and three died. Dr. Algernon T. Bristow of Brooklyn had also reported two cases in which the streptococci were recovered from the blood, and both of these patients were apparently cured by the use of appropriate doses of streptococcus vaccines. Dr. Potter said he had administered the vaccine to Dr. Bristow's cases, and in both the effects of the administrations were so striking that one could not but be impressed with the idea that the vaccine was distinctly curative in its action. Among the other cases seen by the speaker were the following: Dr. J. M. Vancott had also reported two streptococcus cases and Dr. Charles Jewett two puerperal cases, in all four of which the streptococci were recovered from the circulating blood. A number of cases had also been reported in Boston. All of these cases were apparently benefited by the inoculation of the bacterial vaccines. Bassett Smith recently reported a series of cases of Malta fever in which he employed cultures of the organism in small doses, and as the result of his experience he arrived at these conclusions: In the more chronic cases the symptoms were relieved, the course of the disease was shortened, and the opsonic index was correspondingly raised. In the acute cases vaccines had not been found so helpful—in fact, they were injurious oftener than help-

ful. His findings were interesting in view of the relationship between Malta fever and typhoid.

Poliomyelitis Anterior as an Epidemic Disease.—By Dr. Henry W. Berg. (See page 1.)

Dr. B. Sachs said he had hoped that further discussion on this subject of epidemic anterior poliomyelitis would be deferred for at least a year, in view of the investigation that was being made of the subject by a committee appointed for that purpose. This committee was now engaged in the work of analyzing many of the cases that had been reported during the recent epidemic, and when its labors were completed we could expect to learn a great many facts which would render the subject riper for discussion. Dr. Sachs said he could not agree with the idea promulgated by Dr. Berg that the epidemic cases of poliomyelitis anterior were necessarily different from the sporadic, any more than a sporadic case of scarlatina or diphtheria should differ from those seen during an epidemic of those diseases. During an epidemic the virus or toxin of the disease was perhaps more intense or widespread, but we could not make a distinction between the two merely because of the multiplicity of the cases. The chief distinction between the two was that when these cases occurred sporadically we usually had a very imperfect opportunity to study the initial symptoms, while on the other hand during an epidemic the cases were seen earlier and were perhaps more severe. Our earlier conceptions of anterior poliomyelitis were based largely on the late manifestations of the disease, but we were now convinced that it was not at all the same sort of an affection that Charcot and his followers had made us acquainted with. In poliomyelitis anterior there was evidently a very intense infection of the central nervous system, affecting the meninges, the anterior horns of the spinal cord, and at times even the pons and medulla and the central axis of the nervous system. Dr. Sachs said that this fact was hinted at by some writers—including himself—in former years, but it was not until the present epidemic that we had evidence of it. We now had to accept the fact that it was a general infectious disease, and that the form which the infection took varied in different cases. He recalled some cases which had all the features of a multiple neuritis, and a few days ago he saw a boy who had a hemiplegia which came on in the form of an acute infectious disease. He had a facial paralysis, which was part of his hemiplegia, but of the nuclear type, showing involvement of the gray matter of the pons. In relation to the amount of rainfall to the development of these epidemics, to which Dr. Berg had referred, the speaker said that in order to substantiate or disprove that theory Dr. Strauss had communicated with the weather bureau in Washington, asking them to give the amount of rainfall in Sweden for a long number of years. These figures failed to show any marked difference in the amount of rainfall in those years in which the epidemics of anterior poliomyelitis occurred in Sweden and those in which the epidemics failed to occur. This particular point, therefore, required further investigation before any definite inferences could be drawn.

Dr. William M. Leszynsky said he had seen upwards of thirty cases during the present epidemic, and, basing his opinion upon his past experience, it had seemed to him that the cases observed during this epidemic, so far as their clinical manifestations were concerned, were entirely different from the sporadic cases he had seen during the last twenty years. Both in their early and late manifestations they failed to correspond. It was a peculiar fact that while we called this an epidemic of anterior poliomyelitis a very large proportion of the cases, had they occurred sporadically, would not come under that classification. The speaker reported in detail several such cases coming under his observation, in which the symptoms were so anomalous that under ordinary conditions they would never be classified as examples of anterior poliomyelitis.

Dr. Nathan B. Van Etten said that last September he saw six cases of anterior poliomyelitis, four of them in one day and three of them in a single family. The four cases that he saw in one day were in widely separated parts of the city. The three in the same family occurred three days apart. Three of the six cases were severe, although none ended fatally. One patient was still unable to walk, but was making a slow recovery.

Dr. Berg, in closing, said he did not say in his paper that the epidemic cases were different from the sporadic cases; on the contrary, he said that the former were not examples of poliomyelitis anterior at all. He had tried to show by the report of autopsy findings on the early sporadic cases that there was no infection of any organ of the body nor involvement of the central nervous system, except the anterior gray horns in the cord, whereas in epidemic cases there was a general encephalitis and myelitis, with infection of the pia mater and basal ganglia. He intended to indicate that the epidemic cases had not the slightest similarity to the sporadic cases, excepting that the lesion of the latter was in the general pathology of the former. As to etiology, the only point he tried to emphasize was that these various epidemics had apparently occurred in unusually dry seasons. He called attention to the fact that sporadic anterior poliomyelitis was largely limited to children; in fact, it was formerly known as infantile spinal myelitis, whereas 34 per cent. of the epidemic cases occurred in adults. The late Dr. E. C. Seguin, in his lectures on this subject, explained our scant knowledge of the pathology of anterior poliomyelitis by the fact that very few of the patients died, whereas the mortality of these epidemic cases ranged from 18 to 20 per cent. The more closely clinicians studied these cases, the more firmly they became convinced that they were not cases of anterior poliomyelitis at all. They were apparently examples of an acute infectious disease of the cerebrospinal axis involving the meninges, cord, and brain.

Philadelphia County Medical Society.

At a stated meeting held November 13, Dr. C. A. Veasey read a paper entitled "The Treatment of Trachoma." Dr. Alfred Gordon presented a communication entitled "The Pathogenesis of Stump-hallucination apropos of a Case of Twenty-seven Years' Duration," and he exhibited the patient. He pointed out that there are two views as to the origin of the sensation of the presence of an amputated member, one of which attributes it to peripheral irritation resulting from changes in the terminations of the divided nerves; and the other that it has its origin in the cerebrum, representing the memories of sensations received at earlier periods. The hallucination in question lasts for varying periods of time, the longest that Dr. Gordon had been able to find recorded having been twelve years. In his own case a railway laborer had had his arm crushed and amputation at the shoulder-joint had been necessary. The sensation of the presence of the amputated member had persisted during all of the twenty-seven years that had elapsed since the operation, despite the intervention of an attack of hemiplegia affecting the side on which the member had been removed. Dr. Hobart A. Hare read a paper entitled "Some Investigations which Place Well-known Therapeutic Measures upon a Scientific Basis." He cited the fact that experimental observations have been made showing the power of moderate, tonic doses of quinine to increase the phagocytic activity of the polymorphonuclear leucocytes, thus confirming the practice of administering this drug in states of infection. Large doses, on the other hand, diminish phagocytic activity, and are thus capable of doing harm. Dr. Hare himself has demonstrated that moderate doses of alcohol appear to be capable of increasing the bacteriolytic power of the blood. Dr. E. J. G. Beardsley read a paper entitled "The Toxic Effect of Urotropin."

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS, STATE OF COLORADO.

Denver, October 1 and 2, 1907.

TOXICOLOGY.

1. Give symptoms and treatment of chronic poisoning by acetanilid.
2. Name two antidotes to carbolic acid poisoning, and state mode of action of each.
3. Give symptoms of an overdose of wood alcohol.
4. State the toxic effects of the local use of iodoform.
5. Discuss the symptoms and treatment of a patient with mercurial ptyalism or salivation.
6. Mention the treatment of a case of strychnine poisoning.
7. Give symptoms of poisoning by atropine.
8. Name the symptoms of too long continued administration of Fowler's solution.
9. Treatment of an acute case of lead poisoning.
10. Give the symptoms and treatment of poisoning by aconite.

CHEMISTRY.

1. Define (*a*) analysis, (*b*) synthesis.
2. What are (*a*) bases, (*b*) acids, (*c*) salts.
3. Give the preparation and properties of HNO_3.
4. Name the standards based on water.
5. Illustrate why a salt of mercury is incompatible with potassium iodide.
6. What do you understand by carbohydrates?
7. Proteins are compounds of what?
8. How is glycerin prepared?
9. How would you test the gastric contents for morphine?
10. Give a test for indican in urine.

PHYSIOLOGY.

1. Define the science of physiology.
2. Define the terms metabolism, anabolism, and catabolism.
3. Name the digestive ferments, giving origin and function of each.
4. Name the eliminative organs of the body, and tell what is eliminated by each.
5. Define the purpose, chemistry, and mechanism of respiration.
6. What are the functions of the lymphatic system?
7. Define a reflex arc.
8. Give the amount of urine passed per diem by an adult, together with the normal color, reaction, and constituents.
9. How may the amount of urine be physiologically increased or diminished?
10. Give the functions of the skin.

ANATOMY.

1. Give brief description of the vascular anatomy of the arm and forearm.
2. What is the origin of the ovarian arteries?
3. What does the pudic artery supply?
4. Bound Scarpa's triangle.
5. Name the different kinds of joints, giving examples of each.
6. What anatomical structures are divided in making a McBurney incision?
7. What is the nerve supply of the flexor group of muscles of the forearm?
8. What is the origin of the spermatic arteries?
9. What is the origin and insertion of the sartorius muscle?
10. What muscles are attached to the greater trochanter of the femur?

PATHOLOGY.

1. Define pathology.
2. Give the pathological lesions which may result from syphilitic or rheumatic iritis.
3. Define osteomyelitis, and give cause of same.
4. How would you recognize cerebrospinal fluid, and how would you test it in tuberculous meningitis?
5. Give a cause and pathology of pulmonary edema.
6. (*a*) What is necrosis? (*b*) What prevents hemorrhage in gangrenous lesions?
7. What is thrombosis?
8. Give pathology of smallpox.
9. What diseases produce albumin in the urine?
10. Give pathology of lobar pneumonia.

SYMPTOMATOLOGY.

1. Differentiate between tenia solium and tenia mediocanellata, and describe the symptoms which they produce.
2. Give the causes and symptoms of acute intestinal obstruction.
3. Describe the symptoms and conditions that may be observed in a case of sunstroke.
4. Give symptomatology, diagnosis, and prognosis of chronic lead poisoning.
5. Give the symptoms and physical signs of aortic stenosis and mitral regurgitation.
6. Describe symptoms and course of acute lobar pneumonia. Differentiate between lobar and bronchopneumonia.
7. Give the causes, symptoms, diagnosis, and prognosis of acute nephritis.
8. Give the symptoms and diagnosis of renal calculus.
9. Give etiology, symptomatology, diagnosis, and prognosis of arthritis deformans.
10. Give the causes, symptoms, diagnosis, and prognosis of leukemia.

SURGERY.

1. Give the etiology and symptoms of erysipelas.
2. What are the symptoms and treatment of tuberculous peritonitis?
3. Describe a subphrenic abscess, and give the causes and symptoms.
4. Give the early symptoms of hip joint disease.
5. Give the symptoms and cause of hypertrophy of the prostate gland.
6. What is leucocytosis, and its value in surgery?
7. What are the symptoms of fracture of the internal condyle of the humerus, and mention a deformity that may follow.
8. Give differential diagnosis between malignant and benign tumors.
9. What is the cause of dry gangrene?
10. Give differential diagnosis between synovitis of knee-joint and housemaid's knee.

OBSTETRICS.

1. (*a*) What is pregnancy? (*b*) What is fecundation? (*c*) What changes take place in the ovum after fecundation?
2. (*a*) What is the funis? (*b*) What are the dimensions of the placenta and funis at full term?
3. (*a*) What is extrauterine pregnancy? (*b*) Give the symptoms. (*c*) Give the diagnosis.
4. (*a*) What is hydatid pregnancy? (*b*) What are its symptoms and termination?
5. What are the causes of albuminuria and edema?
6. (*a*) What is labor? (*b*) How many stages is it divided into? (*c*) What is the best method of delivering the placenta?
7. How may a child be resuscitated when apparently stillborn?
8. What is meant by "mechanism of labor"?
9. What forms of hemorrhage are met with before, during, or after labor, and treatment of each?
10. (*a*) What are the causes of rupture of the uterus? (*b*) What are the symptoms and what treatment is indicated?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS

BOARD OF MEDICAL EXAMINERS, STATE OF COLORADO

Denver, October 1 and 2, 1907

TOXICOLOGY.

1. Chronic poisoning by acetanilid may give rise to decrease in the number of red blood cells; the face is livid and covered with perspiration, the respirations become slow and shallow, the pulse soft, compressible, and gradually weaker.

Treatment: Stop further administration of the drug, then support the patient by stimulants, warmth, and strychnine.

2. The chemical antidotes to carbolic acid are the soluble sulphates, such as magnesium or sodium sulphate. With the carbolic acid these salts form insoluble sulphocarbolates.

Milk or white of egg is also an antidote, and acts as such by combining with the carbolic acid to form insoluble or nearly insoluble compounds.

3. Symptoms of an overdose of wood alcohol are: Nausea, vomiting, headache, vertigo, dilated pupils, profuse sweating, delirium, coma, and partial or complete blindness.

4. The toxic effects of the local use of iodoform are: Redness, pain, swelling, fever, eruption, general malaise, headache, vertigo, depression of spirits, delusions, mania, drowsiness, coma, death.

5. Symptoms of mercurial ptyalism or salivation are: Profuse secretion of saliva, fetid breath, spongy and tender gums, tender and swollen tongue and salivary glands, may be a blue line on the gums near the teeth, and the teeth may become loosened; there may be nausea, vomiting, diarrhea, cachexia, and collapse.

Treatment consists in removing the patient from the influence of mercury; mouth washes of potassium chlorate or borax, hot baths, mild purgatives and diuretics, potassium iodide, general tonics, and proper hygiene are all indicated.

6. *Treatment of strychnine poisoning*: "The convulsions are to be arrested or mitigated by bringing the patient under the influence of chloral or chloroform as rapidly as possible; the stomach is to be washed out, and the patient is to be kept as quiet as possible." (Witthaus' *Essentials of Chemistry.*)

7. *Symptoms of poisoning by atropine*: Dryness of the mouth and throat, thirst, drowsiness, dysphagia, face flushed, pupils much dilated, eyes prominent, numbness and partial paralysis of the extremities, and there may be delirium and coma.

8. *Symptoms of too long continued administration of Fowler's solution* are: Puffiness of the eyelids, diarrhea, colic, and general abdominal pain, erythema, and possibly neuritis and paralysis.

9. *Treatment of acute lead poisoning* consists in removing the cause and administering the antidote, "magnesium sulphate, which brings about the formation of the insoluble lead sulphate, while the purgative action of the magnesia is also useful. It should be preceded by an emetic, or by the use of the stomach tube." (Witthaus' *Essentials of Chemistry.*)

10. Poisoning by Aconite: "*The symptoms* usually manifest themselves within a few minutes; sometimes are delayed for an hour. There is numbness and tingling, first of the mouth and fauces, later becoming general. There is a sense of dryness and of constriction in the throat. Persistent vomiting usually occurs, but is absent in some cases. There is diminished sensibility, with numbness, great muscular feebleness, giddiness, loss of speech, irregularity and failure of the heart's action. Death may result from shock if a large dose of the alkaloid be taken, but more usually it is by syncope.

"The *treatment* should be directed to the removal of unabsorbed poison by the stomach pump, and washing out of the stomach with infusion of tea holding powdered charcoal in suspension. Stimulants should be freely administered." (Witthaus' *Essentials of Chemistry.*)

CHEMISTRY.

1. (*a*) *Analysis* is the splitting up of a compound into its elements or into simpler compounds.

(*b*) *Synthesis* is the building up of a compound from elements or from simpler compounds.

2. (*a*) *Bases* are ternary compounds capable of entering into double decomposition with an acid to produce a salt and water. *Examples*: Potassium hydroxide, KOH; Calcium hydroxide, $Ca(OH)_2$.

(*b*) *Acids* are compounds of an electronegative element or radical with hydrogen, part or all of which hydrogen they can part with in exchange for an electropositive element, with the formation of a base. *Examples*: Sulphuric acid, H_2SO_4; nitric acid, HNO_3.

(*c*) *Solts* are substances formed by the substitution of an electropositive element for part or all of the replaceable hydrogen of an acid. *Examples*: Sodium nitrate, $NaNO_3$; Monopotassic sulphate, $KHSO_4$.

3. HNO_3 is prepared by the action of strong sulphuric acid on potassium or sodium nitrate:

$$KNO_3+H_2SO_4=KHSO_4+HNO_3.$$

HNO_3 is a colorless liquid, with a strong acid taste and reaction. It is a strong oxidizing agent, and dissolves most metals, with the formation of nitrates. With hydrochloric acid, it forms aqua regia, which is capable of dissolving the so-called "noble metals." In damp air it gives off white fumes When strongly heated it is decomposed into H_2O, N_2O_4 and oxygen.

4. The standards based on water are: (1) The freezing point on the thermometer; (2) the boiling point on the thermometer; (3) specific gravity of solids and liquids; (4) the gram (the unit of weight) and the liter (the unit of volume), with their multiples and fractions; (5) specific heat.

5. Both mercurous and mercuric salts enter into double decomposition with potassium iodide, and a soluble iodide of mercury is produced.

6. *Carbohydrates* were formerly defined as substances of unknown constitution, composed of carbon, hydrogen, and oxygen; the last two being in the proportion to form water.

7. *Proteins* consist of carbon, hydrogen, oxygen, nitrogen, and sulphur, some also contain phosphorus, and a few iron.

8. Glycerin is obtained as a by-product in the manufacture of soap:

$$\underset{\text{Tristearin,}}{(C_3H_5)'''(C_{18}H_{35}O)'_3} + 3\underset{\text{Potassium hydroxid,}}{KOH} = \underset{\text{Glycerin,}}{(C_3H_5)'''H_3} + 3\underset{\text{Potassium stearate,}}{(C_{18}H_{35}O)K}$$

10. *Test for indican in the urine*: The urine is mixed with one-fifth its volume of 20 per cent. solution of lead acetate and filtered. The filtrate is mixed with an equal volume of fuming hydrochloric acid containing 3:1000 of ferric chlorid, a few drops of chloroform are added, and the mixture strongly shaken one to two minutes. With normal urine the chloroform remains colorless, or almost so; but if an excess of indoxyl compounds be present the chloroform is colored blue, and the depth of the color is a rough indication of the degree of the excess. (From Witthaus' *Essentials of Chemistry.*)

PHYSIOLOGY.

1. *Physiology* is that branch of science which treats of the functions of living tissues and organisms in a state of health.

2. *Metabolism* is a name given to the entire series of changes that occur in a cell or organism during the processes of nutrition. It is of two kinds: (1) Assimilative, or constructive, called *anabolism*, and (2) destructive, called *catabolism*.

3.—

Digestive Ferments	Origin	Functions
Ptyalin	Saliva	Changes starches into dextrin and sugar.
Pepsin	Gastric juice	Changes proteids into proteoses and peptones in an acid medium.
A curdling ferment	Gastric juice	Curdles the casein of milk.
Trypsin	Pancreatic juice	Changes proteids into proteoses and peptones, and afterwards decomposes them into leucin and tyrosin; in an alkaline medium.
Amylopsin	Pancreatic juice	Converts starches into maltose.
Steapsin	Pancreatic juice	Emulsifies and saponifies fats.
A curdling ferment	Pancreatic juice	Curdles the casein of milk.
Invertin	Succus entericus	Converts maltose into glucose.

4.—

Eliminative Organs	Substances Eliminated
Kidneys	Urine; which consists of water, urea, uric acid, hippuric acid, creatinine, extractives chlorides, phosphates and sulphates, and other salts.
Skin	Perspiration; which consists of water, urea, sodium chloride, other salts, fats, and fatty acids.
Lungs	Carbon dioxide and water.
Intestines	Feces; which consist of water, nitrogen, hydrogen, carbon dioxide, hydrogen sulphide, methane, undigested food, indigestible matter, bacteria and the products of their decomposition of foods, bile residues, excretin and inorganic salts.
Liver	Bile.

7. A *reflex arc* is a complex made up of: (1) A surface capable of receiving an impression; (2) an afferent nerve; (3) a nerve cell capable of receiving and also of sending out impulses; (4) an efferent nerve, and (5) a surface capable of responding in some way to the impulse convcyed by the efferent nerve.

8. An adult normally passes about 50 ounces of urine daily; the normal color is some shade of yellow; the reaction is acid; for constituents, see above, Question 4.

9. The amount of urine may be physiologically increased by increasing the amount of liquids ingested; and decreased by anything which increases the secretion of perspiration.

10. *The functions of the skin* are: Protection, sense of touch, excretion, regulation of body temperature, absorption, and respiration.

ANATOMY.

2. The ovarian arteries arise from the abdominal aorta.

3. The *superficial external pudic artery* supplies the skin of the lower part of the abdomen and of the penis and scrotum in the male and the labia in the female.

The *deep external pudic artery* supplies the skin of the scrotum in the male and the labia in the female.

The *internal pudic artery* supplies the external organs of generation.

4. *Scarpa's triangle* is bounded *above* by Poupart's ligament; *externally* by the Sartorius; and *internally* by the

inner margin of the Adductor longus; its *apex* is formed by the junction of the Adductor longus and Sartorius. The *floor* is formed, from without inward, by the Iliacus, Psoas, Pectineus, Adductor brevis, and Adductor longus.

6. In making a McBurney incision the following structures are divided: Skin, superficial and deep layers of the subcutaneous fascia, External oblique, Internal oblique, and Transversalis muscles, Transversalis fascia, Subserous areolar tissue, and the Peritoneum.

7. The flexor group of muscles of the forearm is supplied by the median and ulnar nerves.

8. The spermatic arteries arise from the abdominal aorta.

10. The muscles attached to the greater trochanter of the femur are: Gluteus medius, Gluteus minimus, Pyriformis, Obturator internus, Obturator externus, Gemellus superior, Gemellus inferior, and Quadratus femoris.

PATHOLOGY.

1. Pathology is that branch of science which treats of disease; it includes the causes, nature, manifestations, structural changes, and results.

3. *Osteomyelitis* is inflammation of the bone and marrow.

It is *caused* by infection by microorganisms, which may gain entrance by a wound, through neighboring tissues, or through the blood.

4. Cerebrospinal fluid can be recognized by its ability to reduce Fehling's solution.

In tuberculous meningitis the fluid should be centrifugalized and examined microscopically (by stained films); cultures may also be made and a bacteriological examination will indicate the presence of the tubercle bacillus.

5. PULMONARY EDEMA. *Cause*: The cause of edema of the lung is frequently a loss of power in the left ventricle while the right continues to functionate, the extreme degree of stasis attained leading to rapid transudation.

Pathology: The lung is paler than usual, unless at the same time congested; it feels firm, parts of it even resembling hepatized lung, and on section a frothy fluid escapes in quantity; both lungs or a part of one may be involved. With inflammation of part of a lung the rest is apt to become edematous. Pulmonary edema occurs as the final stage of heart and kidney disease and occasionally in alcoholic and insane patients. (From Thayer's *Pathology*.)

6. (*a*) *Necrosis* is the complete and permanent arrest of nutrition in a part; or local death of tissues.

(*b*) In *dry gangrene* hemorrhage is prevented by embolism or thrombosis of the vessels.

In *moist gangrene* hemorrhages are fairly common; in some cases the vessels being eroded the thrombi are expelled; in others there is a hemorrhagic condition due to toxemia.

7. *Thrombosis* is the coagulation of the blood within the vessels during life.

9. Albumin is found in the urine: "(1) In fevers, as typhoid and pneumonia. (2) In valvular heart lesions, degeneration of the heart muscle, diseases of the coronary arteries, impeded pulmonary circulation, in pregnancy by pressure upon the renal veins, in intestinal catarrh and in Asiatic cholera. (3) In purpura, scurvy, leukemia, pernicious anemia, jaundice, diabetes, and syphilis. (4) After taking lead, mercury, iodine, phosphorus, arsenic, antimony, chloroform, cantharides, oxalic, carbolic, salicylic, or the mineral acids, turpentine, and nitrates. (5) In large amounts in acute nephritis, and chronic parenchymatous nephritis; in small amount in chronic interstitial nephritis and amyloid kidney." (Witthaus' *Essentials of Chemistry*.)

SYMPTOMATOLOGY.

1. *Tænia solium*: "The mature worm measures two or three yards in length; a ripe proglottis is about ten mm. long and six mm. broad, with the sexual opening placed laterally; the uterus is coarsely branched. The head, whose size is about the same as the head of a large ordinary pin, has four suckers, often pigmented, and a small rostellum, with a ring of twenty to thirty hooklets. The ova, which are nearly spherical, are readily recognized by their thick shell, with radiating striations. Inside the ovum, when mature, the six hooklets of the embryo may be visible.

"*Tænia mediocanellata* is larger than T. solium, and attains a length of five to nine yards. The ripe proglottides measure sixteen mm. in length by five mm. in breadth, but immature segments are broader than they are long. Very often they exhibit movements after they have been detached from the strobilus and have passed from the bowel. The sexual opening is lateral and the uterus is finely ramified, with frequent dichotomous divisions of the primary branches. The head is rather square in outline and is larger than that of T. solium. It has four suckers, but is devoid of hooklets. The ova closely resemble those of T. solium, but are slightly longer in proportion to their breadth." (From Hutchinson and Rainy's *Clinical Methods*.)

Symptoms are similar in both cases. Often there are no subjective symptoms; there may be dyspepsia, emaciation, ravenous appetite, fetid breath, headache, diarrhea, nausea, vomiting, colicky pains, vertigo, chorea, itching of the nose, and about the anus. The diagnosis is made from finding segments or eggs in the dejecta.

2. The *causes* of acute intestinal obstruction are: Strangulation, intussusception, volvulus, gallstones, tumors, strictures, fecal impaction, foreign bodies, and intestinal paralysis.

The *symptoms* are well shown in the following table (from Gould and Pyle's *Cyclopedia of Medicine and Surgery*):

STRANGULATION	INTUSSUSCEPTION	TWISTS (VOLVULUS)
Subjective Symptoms	*Subjective Symptoms*	*Subjective Symptoms*
1. Generally occurs after age of 20.	1. Most frequent in childhood	1. Most frequent after age of 30.
2. Pain localized, rapid collapse.	2. Constant tenesmus.	2. Pain diffuse
3. Pain intense, paroxysmal in character.	3. Pain develops suddenly and is continuous.	3. Pain paroxysmal, recurs less often than in strangulation
4. Constipation complete.	4. Frequent diarrhea passage of bloody mucus	4. Constipation complete
Objective Symptoms	*Objective Symptoms*	*Objective Symptoms*
1. Temperature often subnormal.	1. Temperature normal or subnormal	1. Temperature slightly elevated
2. Pulse very weak.	2. Same as in strangulation.	2. Same as in strangulation.
3. Stercoraceous vomiting comes on early	3. Same as in strangulation.	3. Same as in strangulation
4. Location in small intestine.	4. Localization in small intestine, bowel frequently protrudes at rectum	4. Location, small intestine, abdomen often protrudes, in certain areas, giving dullness on percussion

6.—

ACUTE LOBAR PNEUMONIA	BRONCHOPNEUMONIA
Generally a primary disease.	Generally secondary to bronchitis or an infectious disease.
Age has little influence.	Generally found in very young or very old.
Sudden onset.	Gradual onset.
Fever is high and regular	Fever is not so high, and is irregular
Ends by crisis between sixth and tenth day.	Ends by lysis, at no particular date.
Generally only one lung affected.	Generally both lungs affected.
The physical signs are distinct; and there is a large area of consolidation.	Physical signs indistinct; and the evidences of consolidation are indefinite.
Sputum is rusty.	Sputum is rather streaked with blood

SURGERY.

3. *Subphrenic abscess*: "A subphrenic abscess is a collection of pus beneath the diaphragm. The pus, as a rule, occupies a part of the lesser peritoneal cavity; in rare instances it is extraperitoneal (when it is of renal origin); in some cases it is contained in the area between the diaphragm, cardiac end of the stomach, and liver or spleen. It is an unusual thing for such an abscess to break into the general cavity of the peritoneum, but it may break into the pleural sac.

"*Causes*: Perforation of a gastric ulcer, perforation of the gall-bladder or gall-ducts, ulceration of the duodenum, diseases of the liver, spleen, pancreas, intestine, appendix, or kidney, hydatid disease, internal injury, metastasis, external injury, caries of rib, or disease of the pleura may be responsible for a subphrenic abscess.

"*Symptoms*: These are the constitutional symptoms of suppuration and a swelling in the subdiaphragmatic region, these symptoms ensuing upon one of the causative conditions before mentioned. In many cases the abscess cavity contains gas as well as fluid. Empyema and subphrenic abscess resemble each other. In empyema the upper limit of the fluid is concave; in subphrenic abscess it is convex. In empyema the flow of pus through an aspirating needle will be most marked during inspiration; in abscess during expiration—the same is true of the rush of gas. In empyema the needle does not oscillate; in abscess it does. The fact that an abscess contains gas is shown by the existence of a tympanic percussion-note over a part of the cavity and an alteration in the area of tympany with an alteration in the position of the patient. An abscess of the liver does not contain gas and alters decidedly the outlines of the organ." (From Da Costa's *Modern Surgery*.)

4. *The early symptoms of hip-joint disease* are: Night cries (in a child); lameness in the morning; a slight limp; tendency to become tired on slight exertion; wasting; spasm; pain; swelling; and deformity (either real or apparent).

5. *Symptoms of hypertrophy of the prostate gland*:

Slowness in starting urination; difficult micturition; frequency of micturition, particularly at night; the presence of residual urine; dull, aching pain in the perineum and above the pubes; enlargement of the lateral lobes of the prostate; there may be cystitis and retention of urine.

The *cause*: It is a senile change, and may be due to increase of the glandular substance or of the interstitial fibrous or muscular tissue.

7. *In fracture of the internal condyle of the humerus*: The fragment forms a projection at the back of the elbow; if the swelling is not too great, crepitus may be elicited by flexing and extending the forearm; preternatural mobility exists; the space between the condyles is increased; the forearm bends towards the ulnar side; and the "carrying function" is lost.

8. *Malignant tumors* are not encapsulated, tend to infiltrate the surrounding tissues, give rise to metastatic growths, have a tendency to recur after removal, give a cachexia, have a fatal tendency.

Benign tumors are encapsulated, do not tend to infiltrate the surrounding tissues, do not give rise to metastatic growths, do not tend to recur after removal, do not produce cachexia, and do not have a fatal tendency (except from their location).

9. The *cause of dry gangrene* is: Deficiency of arterial blood.

10. In *synovitis of the knee-joint* the effusion is behind the patella, the patella is lifted up by the effusion, and floats.

In *housemaid's knee* the swelling is in front of the patella, the patella does not float, and the joint is not affected.

OBSTETRICS.

1. (*a*) *Pregnancy* is the state of being with child, or the state of the woman from conception till the product of conception is expelled.

(*b*) *Fecundation* is the union of the spermatozoon with the ovum.

2. (*a*) The *funis*, or umbilical cord, is a cord-like structure extending from the umbilicus of the fetus to the placenta.

(*b*) At full term the *placenta* is from six to nine inches in diameter, about three-quarters of an inch in thickness at the central point, and weighs about one pound; the *funis* is about eighteen inches long, and about a quarter of an inch in thickness. All of these measurements are liable to considerable variations.

3. *Extrauterine pregnancy* is a pregnancy in which the ovum is developed outside of the uterine cavity.

"When extrauterine pregnancy exists there are: (1) The general and reflex symptoms of pregnancy; they have often come on after an uncertain period of sterility; nausea and vomiting appear aggravated. (2) Then comes a disordered menstruation, especially metrorrhagia, accompanied with gushes of blood, and with pelvic pain coincident with the above symptoms of pregnancy; pains are often very severe, with marked tenderness within the pelvis; such symptoms are highly suggestive. (3) There is the presence of a pelvic tumor characterized as a tense cyst, sensitive to the touch, actively pulsating; this tumor has a steady and progressive growth. In the first two months it has the size of a pigeon's egg; in the third month it has the size of a hen's egg; in the fourth month it has the size of two fists. (4) The *os uteri* is patulous; the uterus is displaced, but is slightly enlarged and empty. (5) Symptoms No. 2 may be absent until the end of the third month, when suddenly they become severe, with spasmodic pains, followed by the general symptoms of collapse. (6) Expulsion of the decidua, in part or whole. Nos. 1 and 2 are *presumptive signs;* Nos. 3 and 4 are *probable signs;* Nos. 5 and 6 are *positive signs.*" (*American Text-book of Obstetrics.*)

4. (*a*) *Hydatid pregnancy* is a pregnancy in which the chorionic villi undergo a proliferating degeneration with the production of a mass of cysts attached to the placenta. These cysts look like bunches of grapes.

(*b*) The pregnancy begins as in normal cases, but in about the third month the uterus becomes suddenly and rapidly enlarged; irregular uterine hemorrhages occur; and there is a discharge of fluid containing the vesicular growths; labor occurs, and the mass of cysts is expelled.

6. (*a*) *Labor* is the process by which a pregnant woman expels the product of conception at or near term.

(*b*) Three stages.

(*c*) Crede's is the best method of delivering the placenta.

8. "By the *mechanism of labor* we understand the operation of the mechanical *forces* and the execution of the mechanical *movements* necessary to secure the passage of the child through and its exit from the parturient canal." (From King's *Obstetrics.*)

9. The following (from Gould and Pyle's *Cyclopedia of Medicine and Surgery*) is a useful classification of the hemorrhages in question:

A. Hemorrhages of Pregnancy: Caused by (1) placenta prævia; (2) premature separation of a normally situated placenta; (3) apoplexy of the decidua or placenta.

B. Hemorrhages of Labor: Caused by (1) placenta prævia; (2) premature separation of a normally situated placenta; (3) relaxation of the uterus; (4) laceration of the cervix; (5) rupture or inversion of the uterus.

C. Hemorrhages of the Puerperium: Caused by (1) retained secundines; (2) displaced uterus; (3) displaced thrombi; (4) fibroid tumors; (5) hypertrophied decidua; (6) carcinoma.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.	
Alabama*	W. H Sanders, Montgomery	Montgomery	Jan. 7

* No Reciprocity recognized by these States.

† Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

North Carolina.—The North Carolina State Board of Medical Examiners recently adopted the following rules governing reciprocity in accordance with a State amendment to the Practice Act: (1) The applicant must have a diploma from a medical college requiring a three years' course of study for such degree. (2) He must have a license from a State Board of Examiners requiring the same per cent. as this State, which is 80. (3) He must present a sworn affidavit from two practising physicians as to his professional standing in his community. (4) The burden of proof shall rest on the applicant. (5) He shall attend the meeting of the Board at the time of application and make application in person. (6) He shall pay a fee of $10 for his license.

New York and Ohio.—An agreement in reciprocity in medical licensure between the States of Ohio and New York has been signed by the authorities of these States. Certificates gained by examination only are to be considered. Each State reserves the right to examine into the qualifications of the applicant, and may also demand the original credentials and papers before granting a license.

New Instruments.

A NEW BONE-DRILL AND BONE-WRENCH.

By CARL BECK, M.D.,
NEW YORK.

WHILE modern techniques show a decided tendency towards eliminating force from its strategy everywhere, great allowances are still made in regard to bone-surgery, many bone-instruments carrying the expression of brutal tendencies on their exterior. Their manipulation generally requires more or less force, as for instance the well-known and otherwise useful drills of von Langenbeck, Hamilton, Brainard, Collin, etc., especially if they are employed in large bones and if there is much calcareous matter in the cortical layer. A drill, therefore, which would obey the intentions of the surgeon by light-handed motion would surely be preferable. I find

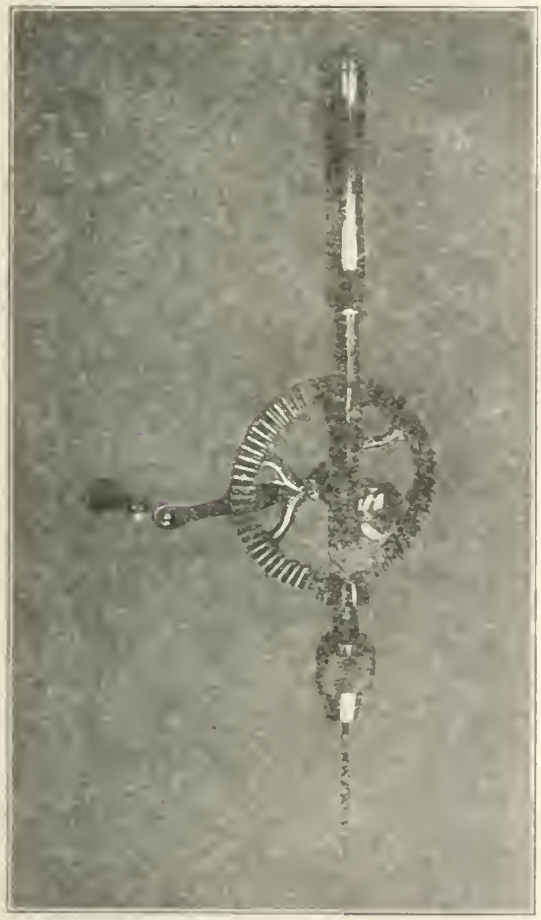

FIG. 1.

that a modified carpenter's gear-drill (Fig. 1) answers this purpose admirably, as it is not worked by pressure but by simply rotating the handle. Thus, rapid motion is made possible. Instead of the common carpenter handles, I utilized the Collin principle, also providing the crank handle with a ball and socket joint so that the instrument can be folded. In place of the drills which are commonly used by plumbers, I selected the spiral shape of the carpenter's drill, which permits of much easier penetration of the bone substance. The tips of the drills are sharp, as we see them in drill trephines. They are fastened to the holder by a large spiral ring, not by the traditional lateral screw. Thus a firm attachment is secured, the drill never becoming loose or displaced, as so frequently happens if the usual combination is used. Three drills of various sizes answer the purpose. As I use bronze-aluminum wire exclusively, I find the smallest size large enough to bore the hole required for introducing the thin wire. A circular screw is to be attached as a guard for the regulation of the penetrating distance in special cases, as for instance in trephining. For the latter purpose, however, a larger drill trephine is used, which is constructed after the same principle. The danger of breaking the drill is excluded, since force is not applied.

FIG. 2.

Fig. 2 represents a bone-wrench, the jaws of which are elongated in a beak-like shape in order to grasp the bone in its entirety as well as in sections. The grasp is absolutely firm, and the assistant does not need to use any amount of force after the instrument is attached, so that he is able to hold it as long as required without unnecessarily augmenting the insult to the bone, and last but not least, without exhausting himself. In severing bones by saw or chisel, or by performing partial resections, and especially in operations for malunion of fractured bones, this instrument has done me splendid service.

Both instruments are of nickel-plated metal and can be sterilized without interfering with their usefulness. They were made by the Kny-Scheerer Company.

I take this opportunity to mention that in severing deformed bones by the chisel, as is sometimes required in malunion at the lower end of the radius, the larger as well as the smaller handle of my abdominal spoon (see MEDICAL RECORD, February 4, 1905) may be conveniently used as a protection of the soft tissues against the chisel when introduced underneath the exposed bone.

Ankylostomoanemia in Children.—Olimpio Cozzolino classes *Ankylostoma duodenale* as one of the intestinal parasites that are dangerous to the life of the host. Parasites may do harm by subtraction of albumin from the organism in sucking blood from the intestines and cause hemorrhage from the wounds. They may migrate into the internal organs. They may act mechanically as extraneous bodies. They may poison the patient by absorption of their life products, or they may aggravate any intercurrent affection by the debility which they produce. The author describes two fatal cases observed by him. They came from a family, all the members of which showed the presence of ankylostoma in the stools. Their presence caused a high grade of anemia. The parasite is cylindrical, grayish-red, measuring from 8-12 millimeters in length. It is provided with four hooks, by which it fastens to the intestinal wall for the purpose of sucking the blood. The number of eggs is enormous, four million having been found in one stool. As larvæ they maintain their vitality outside the body for about fifty days. They are carried to the new host by means of unclean hands and infected water. According to some the anemia is produced by constant abstraction of blood from the system, while others think that they produce a poison which is a source of intoxication to the body. The white blood corpuscles are many of them destroyed, and there is eosinophilia and increase of leucocytes. The diagnosis is based on the anemia and the presence of the parasites in the stools, and of eosinophilia. The treatment consists of an energetic course of anthelmintics. Even after the parasites are removed the anemia may cause death. *La Pediatria.*

Books Received.

The Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

PLAGUE.

BY ALVAH H. DOTY, M.D.,

HEALTH OFFICER PORT OF NEW YORK.

THE unfavorable reports which are frequently published relative to the presence of plague in India and other sections of the East have caused some uneasiness in this country, particularly as outbreaks of this disease have occurred in San Francisco and vicinity during the past four or five years. While there is probably no doubt as to the accuracy of these reports or that the plague has caused great loss of life in the countries above referred to, it must not be assumed that the same result would follow its appearance in the United States, or in any other civilized country where modern sanitary regulations are enforced and where the people are intelligent, and not only observe, but aid in the enforcement of sanitary regulations. As the result of ignorance and a peculiar religious creed, the native population of India deliberately and seriously obstruct health officials in the performance of their duties; besides the individual resisting power of these people against disease is at the lowest ebb, owing to the existing poverty, overcrowding, etc. Therefore, it is not strange that plague in India and elsewhere in the East should extend with great rapidity and involve a very large mortality.

History presents reliable evidence to show that plague was recognized soon after the beginning of the Christian era, and probably before this period, and that it has frequently appeared in different sections of the East and occasionally in Western Europe. It is undoubtedly the disease which swept over Europe during the fourteenth century under the name of the "black death" and caused great loss of life and led to the establishment of the first official quarantine, which occurred in Venice in 1348, and was followed by similar regulations at other Mediterranean ports for the purpose of securing protection against this disease on its way from the East. Until 1896 plague had not appeared in Western Europe for many years. The outbreak at this time followed an active revival of the disease in India and China, particularly in Hong Kong, in 1894. Prior to this period we possessed practically no scientific knowledge of this disease either in regard to its cause or means of transmission. During the Hong Kong epidemic, Kitasato and Yersin, working independently of each other, discovered the specific organism of plague. Subsequent investigation has presented numerous theories as to the means by which this disease is transmitted, the most prominent one being that it is the rat through the medium of fleas. Some believe that the disease is transmitted to man only in this way and not from one person to another, while other investigators declare that the disease may in various ways be transmitted from one person to another and that the rat is not always responsible for its appearance. Recent experiments have also shown that monkeys, squirrels, cats, and other animals, and also bugs, cockroaches, flies, mosquitos, etc., may directly or indirectly act as a medium of transmission. It is also claimed that infection takes place through the respiratory and digestive tracts. This mass of evidence, some of which is contradictory, will require considerable time for careful analysis. In the meantime I believe it to be unsafe to give undue prominence to any theory which may minimize the danger of the transmission of this disease from one person to another. Plague frequently appears in a mild or unrecognized form; as an instance of the former, I may cite the following:

On November 18, 1899, the steamship *James W. Taylor*, a freight vessel, arrived at the New York quarantine station from Rio Janeiro, where an epidemic of plague existed. The captain reported that a member of the crew had died in transit and was buried at sea, but that otherwise all were well on board. A visual examination alone would probably have confirmed this statement, as all reported well and appeared on deck for inspection, but when the temperatures of the crew were taken, their clothing removed, and a glandular examination made, a mild case of bubonic plague was detected. The patient not only recovered, but at no time during his detention at Swinburne Island was it necessary, so far as his physical condition was concerned, to confine him in bed, and he repeatedly stated that he did not feel very sick. If this case had not been detected, and if as a result secondary cases had occurred after the patient had reached New York, the outbreak would undoubtedly have been attributed to some other means of infection. It may be added that the cargo of this vessel was removed at quarantine and all dead rats which were found after sulphur dioxide had been generated in the hold of the vessel were carefully placed in metallic receptacles and taken to the laboratory for examination, but no evidence of plague was found among them.

While every sane and practical means should be taken to protect against the presence of presumably infected rats, either on shipboard or on land, we are not justified in carrying out regulations which are unreasonable and which unnecessarily cripple commerce or the public, besides we must not forget that plague may be transmitted in other ways than by the rat.

The history of outbreaks of plague and other infectious disease furnishes conclusive evidence that the results which follow their appearance depend principally on the means which are taken to prevent their extension. Even simple measures of protection are sometimes followed by the most satisfactory results. A notable and well authenticated instance of this occurred in 1656, during the out-

break of plague in Italy, particularly in Naples and Rome, both populous cities. In the latter place the measures which were carried out for the protection of the city were under the personal supervision of Cardinal Gastaldi, who was exceedingly energetic in his efforts to enforce cleanliness, prevent overcrowding, etc. The result of his work was very significant. While plague caused 300,000 deaths in Naples, it caused but 14,000 deaths in Rome. There can be no reasonable doubt that the measures taken by Cardinal Gastaldi were largely responsible for this result, as the mortality at Naples corresponded to the mortality which occurred during outbreaks of this disease at this period in other sections of Europe.

The outbreak of plague in Europe in 1896 involved within a comparatively short time ports in Scotland, Portugal, Australia, South America, and other places. These outbreaks were met by regulations dictated by modern sanitation and not in one instance did the disease get beyond the control of the health officials in charge, and the outbreaks disappeared without serious loss of life, whereas the appearance of plague in Europe during the fourteenth century is estimated to have destroyed about one-quarter of the population and extended over a period of twenty years or more.

The present outbreak of plague in San Francisco appeared in August of this year. Thus far there have been only 112 cases. The treatment of this outbreak has been under the supervision of the United States Public Health and Marine Hospital Service, and the results are very creditable to those in charge and show what modern sanitary methods can accomplish even in a community which has not yet recovered from a recent serious disorganization.

There is no doubt that outbreaks of typhus fever, commonly known as "ship-fever," etc., a disease more actively infectious than plague, have in earlier times been mistaken for plague and have under certain conditions caused loss of life almost equal to the latter disease.

The horrors of the Irish famine, which occurred between 1813 and 1818 are probably forgotten. The unusually cold weather during these years had practically destroyed the potato and other crops; thousands of families were rendered homeless and obliged to seek food wherever they could, and many cases of destitution and starvation occurred. Typhus fever appeared during the latter part of 1816, and rapidly increased. It is estimated that 800,000 cases occurred in Ireland during this epidemic representing about one-eighth of its population. Seventy thousand, or about one-third of the population of Dublin, contracted the disease. It is a significant fact that this disease did not disappear until after the abundant harvest of 1818. I am quite sure that plague during the fourteenth century did not cause much greater local devastation than that which occurred in the outbreak already referred to. Typhus fever has a number of times visited New York City. The last outbreak occurred in 1892-3. It appeared abruptly among the foreign population in the closely packed tenement houses in the lower section of the city on the east side, and subsequently in the Bowery lodging houses, which were filled with men of the lowest class, who were without homes and who were constantly moving from one place to another, constituting a most dangerous medium of infection. The Department of Health began at once an exhaustive inspection to trace the origin of each case brought under observation and also to detect the whereabouts of new cases. Disinfection and other sanitary measures were rigidly enforced, and as a result the disease completely disappeared within a few months. This outbreak was limited to about 700 cases and all but a very few of them were among the lower class. The latter illustrates the fact familiar to all practical sanitarians that epidemics of plague, typhus fever, etc., are almost always confined to sections where filth, overcrowding, and poverty exist. This was shown in the London outbreak of plague in 1664, when the disease was so noticeably confined to the lower classes that it was called the "poor man's plague," and in the outbreak of plague which occurred in Canton in 1894, which caused the death of 30,000 natives, while none of the 300 American and English residents were affected. This proves that when modern sanitary regulations are carefully enforced, particularly in communities where people aid rather than obstruct the efforts of public health officers in the performance of their duties, outbreaks of infectious disease can surely be brought under control and that the ravages which they have caused in the past need never occur again. Practical experience has presented indisputable evidence of this, and the lesson to be learned is that proper sanitary regulations should be enforced in every city and town, and that the latter should be equipped and prepared to meet emergencies, and not to depend on organizations formed for this purpose after the disease has appeared.

In referring to this subject, it is not my intention to belittle in any way the danger that outbreaks of infectious disease may involve, but to emphasize the fact that the results which follow their appearance depend principally on the means which are taken to prevent their extension, and that so far as plague is concerned, the very unfavorable reports which come to us from India and other sections of the East must not be accepted as an indication of what would follow an outbreak of this disease in the United States, or in any other part of the world where modern sanitary regulations are enforced.

THE RENAL COMPLICATIONS AND SEQUELÆ OF INFLUENZA.

By HEINRICH STERN, M.D.,

NEW YORK.

Renal disease as the sequence of the influenzal poison has not as yet found that consideration which its importance demands. Two reasons may be assigned for this evident disregard, first, the neglect to recognize the minor renal affections which, for convenience sake, we may group together as "congestion" and, second, the little attention habitually bestowed upon the patient as soon as the more prominent phenomena of the influenza have disappeared.

Acute nephritis in its pronounced forms, it is true, is a comparatively infrequent concomitant of the influenzal affection. Nephritic conditions of as pronounced a character as we are wont to find them in scarlatina, diphtheria, pneumonia, and other acute infectious diseases are not every-day occurrences in influenza. The morbid changes in the kidneys during or shortly after an attack of the grippe are, if they occur at all, mostly of a lesser degree. This fact must be ascribed to the slight virulence of the influenza poison for the kidneys. While, however, the influenza poison possesses no great toxicity for

the kidneys its influence upon them seems to endure; at least, the more pronounced renal lesions are usually not observed until long after the subsidence of the acute syndrome of the infection.

I distinguish three forms of renal complications of influenza: (1) Cases with acute symptoms of renal involvement; (2) Cases in which occurs an aggravation of pre-existing renal disease; (3) Post-influenzal nephritis.

The *acute renal involvement*, as stated before, is mostly of a decidedly milder character than in some other infectious diseases. At the height ot an attack of influenza the renal symptoms are, as a rule, less pronounced than when the attack has somewhat abated. Degree and character of the acute renal symptoms point to a state of active congestion in the great majority of the cases. This active hyperemia of the kidneys, as a matter of course, is nothing else but a toxic irritation, the very first stage of an inflammatory process, which may subside as soon as the influenza poison has become definitely eliminated from the organism. However, while the influenza poison is not apt to inflict great injury upon the kidneys by its direct toxicity, we have abundant evidence that influenza bacilli may be retained in the body in a latent state for months and even years, that they may become periodically active, and that they may thus keep up—spasmodically so to speak—the inflammation of an organ which may ultimately lead to its destruction. Fortunately, the influenza germs and toxins are eradicated from the organism, or are rendered innocuous within a comparatively short period and the normal renal circulation is soon reestablished in the vast proportion of all the instances.

Active renal hyperemia of influenzal origin manifests itself in a similar manner as if it occurred on the basis of any other toxic invasion. There is the dull aching soreness in the infrascapular and lumbar regions which becomes more acute and circumscribed upon pressure, there is the rather frequent and occasionally tenesmic urination, the slight hematuria, the insignificant serum-albuminuria and globulinuria, the smaller or larger number of renal epithelia and last but not least an occasional narrow hyaline cast.

The moment the influenza poison is eliminated or neutralized, all these phenomena disappear as a rule, and the renal incident of influenza closes there and then.

In other cases, probably not more than from 2 to 4 per cent. of all instances of influenza, the active renal congestion assumes the character of the catarrhal nephritis of Virchow or turns into a genuine glomerulonephritis. These severer forms of active renal hyperemia do not differ much clinically from simple congestion excepting that the various urinary abnormalities may become somewhat accentuated. All the urinary solids, including urea, are continued to be excreted in normal amounts, although the output of urinary water may become increased or decreased as the case may be. Again, clinical differentiation between the various degrees of active renal hyperemia cannot be attempted in many instances.

Acute diffuse nephritis, the genuine acute Bright's disease, according to all available statistics, is a rather infrequent complication of the pyretic stage of influenza. It appears somewhat more frequently at the termination of the influenzal process when it may be the result of a protracted renal congestion. Its presence is characterized by anasarca of the limbs and trunk, effusion into the serous cavities, a recrudescence of the febrile condition, violent headache, hard pulse and high arterial tension, and pain and pressure pain similar to that of active renal hyperemia in the lumbar region. Uremic manifestations may be also not missing. The urine is very much diminished in quantity, its density at the outset is increased; in color it is very dark, resembling Vogel's urinary tints Nos. 7 and 8. Its transparency is decidedly impaired and it deposits on standing a sediment not unlike that from beef-tea. The total urinary solids excreted in the twenty-four hours are invariably diminished, urea being that urinary constituent the elimination of which is most markedly reduced. Serum-albuminuria is profuse, and hematuria in various and varying degrees is always present. Large numbers of renal epithelia and casts (the latter carrying epithelia and blood constituents) are found without fail in the urinary sediment.

In other instances, the renal affection may assume the character of an acute diffuse nephritis in a more direct manner, namely, by the rapid invasion of the kidneys by virulent influenza microbes. In such cases, simple renal congestion lasts but a very brief period.

The second variety of renal complication of influenza, the *aggravation of preexisting renal disease*, is of decided importance as far as prognosis is concerned. An intercurrent renal congestion—such which is liable to occur during an attack of influenza or when it declines—may often arouse a latent nephritic condition into an active, progressive and destructive process. Again, when there exists an active nephritis its complication by influenza is apt to bring about a speedy fatal issue.

I remember some cases in children in which the apparently healed nephritis of scarlatinal origin had been stimulated into renewed activity by an intercurrent influenza. I know of a case of nephritis which had followed a lobar pneumonia and which had been entirely quiescent for three years until an attack of influenza caused its recrudescence. A second attack of influenza a year later again caused an aggravation of the nephritic symptoms. Many cases of transitory or intermittent albuminuria really belong to this category. In such cases there is often a history of an antecedant acute renal disease which to all appearances had vanished, but a close observation will show that recurrence or augmentation of the albuminuria oftentimes takes place in the wake of intercurrent affections.

Patients with inherent or acquired predisposition to renal disease often perplex the most experienced practitioner. To-day, the patient may not exhibit any nephritic symptoms whatsoever, and next week after a slight febrile condition he may present all the earmarks of acute uremia. The uremic symptoms may subside and the former latency of the nephritis may be reestablished, but, must the physician ask himself, what caused this aggravation; was the intercurrent pyrectic affection at its foundation or was this pyrexia nothing but an expression of the renewed activity of the nephritic process?

As a matter of fact, recrudescence of latent nephritis is called forth by intervening diseases in a goodly proportion of the cases. The conscientious and thorough examiner for life insurance is well aware of this when he asks the applicant, whose nephritic condition seems rather young, to present himself for another examination after a certain period. For the past ten years I have had a very large experience with applicants for life insurance who were rejected or whose acceptance was post-

poned on account of renal disease. Most of these proposers for life insurance were unaware of their kidney affection when they underwent the first examination by the company's physician, and their family physician, in many instances assured me that up to a few weeks ago there was absolutely no evidence of a renal lesion. That the applicant for insurance had been meantime in the throes of the grippe or another acute disease which may have given rise to the impairment of the kidneys or to an aggravation of a latent symptomless nephritic state, had not been taken into consideration. And, of course, to the drugs which were administered for the acute disease and which act often as renal irritants no influence whatsoever was ascribed as regards the production or the aggravation of the renal phenomena.

Patients upon whose system chronic nephritis of whatever kind has made deep inroads frequently succumb to intercurrent influenza. This, however, is an occurrence which, strictly speaking, does not belong to the present consideration, as here the influenza is a complication of a progressive and destructive nephritic process, and not, as in aforementioned instances, in which the renewed activity of a quiescent renal affection is a concomitant or a sequela of influenzal invasion.

The *third class* of renal complications of influenza may be regarded as post-influenzal in its production. In a certain sense, the nephritides of the first class also belong to this category in as far as they hardly ever originate during the increment but most always at the decline of the acute grippal symptoms. Still, there is that difference that post-influenzal nephritis appears as a rule after all the symptoms of influenza have subsided, often even after the patient has materially recuperated from the attack, and that its course tends to chronicity. Post-grippal nephritis should therefore be looked upon as a phenomenon of re-infection in many instances.

Post-influenzal nephritis is less of a complication than a sequela. It may disappear after two or three months but it is usually of a persistent and chronic nature. If it becomes permanent it assumes mostly the character of chronic interstitial degeneration. I have seen a few cases of undoubted post-influenzal nephritis in which occurred considerable suppuration. Some other cases exhibited the clinical and urinary features of a combination of diffuse and interstitial inflammation. In not a single instance, however, of chronic renal disease with no etiological history excepting an antecedent influenza, did I find the specific characters of chronic parenchymatous nephritis *per se*.

I am verily of the opinion that the majority of chronic interstitial nephritides, not due to constitutional causes, is the consequence of an acute infectious disease. As chronic interstitial nephritis does not make itself evident by large amounts of serum-albumin or by the inevitable presence of tubular casts, or by pronounced edematous swellings, its existence is often not suspected for a long time. Renal disease with no or but vague clinical symptoms can often be demonstrated by functional diagnosis alone, that is by the determination of the degree of renal activity. In cases of long protracted convalescence from an attack of influenza, or in instances of gradual bodily decline after this infection, I think it imperative to ascertain the state of renal efficiency. This is readily accomplished by the phloridzin method. I inject hypodermatically 0.01 gram phloridzin and expect to obtain thereby from the normally functionating kidneys a minimum of about 1.6 gram glucose within three and a half to four and a half hours. Fourteen cases of protracted convalescence and general systemic decline after influenza examined by me from three to ten weeks after abatement of the acute syndrome during last winter and spring showed the following results as regards their renal efficiency:

Sex	Age	Duration of Acute Symptoms	Time elapsed since abatement of acute symptoms	Urinary Features	Phloridzin Glucose, Gm.	Renal Efficiency
F.	31	8 days	5 weeks	Nothing abnormal.....	0.58	Impaired.
F.	35	4 "	3 "	Slight alb. renal epith.	1.25	Sl'tly imp'd
M.	47	14 "	3 "	Normal.....	0.5	Impaired.
M.	29	10 "	10 "	Alb. casts. epith.....	None	Insufficient
M.	33	5 "	3 "	Nothing abnormal....	2.39	Good.
M.	58	16 "	5 "	Nothing abnormal....	0.8	Impaired.
M.	48	14 "	4 "	Nothing abnormal....	2.08	Good.
F.	37	6 "	4 "	Slight albuminuria....	0.68	Impaired.
M.	28	7 "	6 "	Nothing abnormal..	1.28	Slt'ly imp'd
M.	18	4 "	3 "	Slight albuminuria....	1.72	Normal.
F.	30	12 "	5 "	Pus, pelvic epith	0.43	Impaired.
F.	44	10 "	4 "	Nothing abnormal	0.64	Impaired.
M.	61	14 "	4 "	Alb. casts, ren. epith.	None	Insuff'nt.
M.	60	8 "	3 "	Nothing abnormal...	1.06	Impaired.

Of these fourteen sets of kidneys only three pairs functionated properly, two pairs exhibited slightly diminished activity, in seven instances the efficiency was decidedly impaired, and in two instances the renal function proved entirely insufficient. The slow convalescence, or the systemic decline, could be accounted for—in part at least—by the renal insufficiency or, in other words, by the invasion of the kidneys on the part of the influenzal poison.

INFLUENZA OF THE NOSE, THROAT, AND LARYNX.

By W. SOHIER BRYANT, A.M., M.D.,

NEW YORK.

This disease is due to a specific infection caused by the influenza bacillus and is distinctly contagious. The bacilli gain entrance to the body through the mucous membrane of the upper air tract, usually passing in *via* the lymphoid tissue of the nasopharynx or of the lateral wall of the pharynx and tonsils.

The pathological changes caused by the influenza bacillus are due to local infection and general toxemia and septicemia. Locally there is a submucous serous exudation and edema of the mucous membrane, with occasionally a thin loosely adherent fibrous exudate. Small hemorrhages sometimes occur in the mucous membrane. In the later stages, the mucous secretion becomes purulent and contains a variety of pathogenic organisms. There may be some loss of epithelium and the expectoration may be slightly tinged with blood.

The period of incubation is short and the immunity following an attack is also of short duration. The onset is rapid, ushered in with local pain and swelling and tenderness, with high temperature and marked general prostration.

There are pains in various parts of the body, chiefly in the head, throat, and back of neck. The pains in the head and face appear to be due to acute swelling of the mucous membrane of the various sinuses and closure of their ostia. The mucous membrane is moist, pale, and edematous without much change in the mucous secretion. From the point of entrance, the infection passes both up and down through the mucous membrane, sometimes widely extending. After from thirty-six to seventy-two hours, the violence of the acute symptoms be-

gins to decrease; mucous secretion increases and becomes more or less purulent; the edema diminishes, the mucous membrane becomes red, and sometimes its surface is slightly abraded. The progress to recovery is slow and marked by the continuance of mental and muscular weakness and general depression.

The diagnosis is easily made on the clinical picture. In atypical cases or cases due to mixed infection the diagnosis is sometimes difficult. If the influenza bacillus is found in abundance in the expectoration or tissues, the diagnosis is positive.

Complications or sequelæ frequently occur. The complications that fall within the scope of this paper do not include those affecting the alimentary tract, the general nervous system, the kidneys, the lungs, or the ears. Metastatic infections sometimes occur. We may consider, however, those complications which not infrequently appear in the nose and its accessory cavities, in the throat, and sometimes in the larynx. In the nose, influenza often causes sufficient engorgement and edema to close the fossæ and prevent nasal breathing, and to interfere with the normal olfactory functions. The contact and pressure within the nose cause reflex nervous symptoms of the higher centers and cortex of the brain, with aprosexia and kindred phenomena. The swelling of the nasal mucosa may close the ostia of the various air sinuses and ear. Severe headaches or face aches characteristic of the sinuses affected, result. The inflammation of the sinus may go on to suppuration which may become chronic. A mixed infection is found in these cases. The severity of the complications arising in the accessory sinuses of the nose is usually in proportion to the malformation of the bony and cartilaginous structures of this region or to hypertrophy of the soft parts. The inflammation may be confined to one sinus but usually affects many, all on one side and one or two on the other side. Usually at first there is more or less pain referable to the sinuses, which subsides in a day or two to reappear a few days later with more definite symptoms of sinusitis and empyema involving several sinuses. The pains are now more severe and are more definite in location and tenderness is usually marked. The frontal and maxillary sinuses give definite signs, local pain and tenderness, and opacity on transillumination. The ethmoid and sphenoidal sinuses, however, are more difficult of access owing to their comparatively deep location. The symptoms of involvement of these sinuses are extreme local intranasal tenderness and increased discharge, sometimes associated with pain deep in the head and in the vertex or back of head and neck.

In the throat, the influenza may cause inflammation of the tonsils and when certain other pathogenic bacteria are present, tonsillar or peritonsillar abscess may result.

In the larynx, the edematous swelling is sometimes sufficient to make tracheotomy imperative. Usually pain and cough are the only local symptoms which distress the patient. Aphonia is not the rule.

The prognosis is good for entire recovery in one to six weeks, except when complications arise or when the infection is specially virulent and the patient is previously debilitated. In the latter case, a fatal issue may occur from exhaustion or as a result of complications. The prognosis of complications in the accessory sinuses is good in all except neglected cases. When treatment is commenced early, surgical necessities are usually avoided and the chronic condition is prevented. If treatment is not commenced in the incipiency of the complication, minor nasal operations are usually sufficient to prevent the establishment of a chronic empyema. After the chronic condition has commenced more or less radical surgical means are necessary for a cure, to relieve the local and general strain on the patient, and to avoid the danger to life from cranial extension or metastatic or systemic infection.

The treatment is abortive, local and general, besides the treatment of the complications. The abortive treatment consists in the local use of astringent antiseptics which sometimes abort and often ameliorate the virulence of the infection if they are applied immediately on the appearance of the first sign of local discomfort, pain, or edema. Nitrate of silver in ten per cent. solution, painted on the affected area has given me much satisfaction. Alcohol 99 per cent. with equal parts of glycerin has worked nearly as well.

Local treatment is directed to the relief of the edema, assuaging pain and tenderness, and cleansing and partially sterilizing the mucous surfaces. In the nose and throat this may be accomplished with nitrate of silver; a solution in strength of from 2 to 5 per cent. applied with a swab has given me the best results. Argyrol, up to 30 per cent., on a swab is good. When there is a false membrane, a spray of hydrogen peroxide is indicated. After the acute stage is passed and the edema gone, a spray of Dobell's solution seems to facilitate expectoration of the mucopurulent secretion. When the discharge has lessened, an alkaline aromatic spray is desirable to finish up with. A peroxide of hydrogen gargle is indicated for the throat if a purulent condition exists there. In the larynx, the applications must be considerably reduced in strength. Silver nitrate in 2 per cent. solution can be applied with a swab or spray after cocainization. Alcohol 95 per cent., and glycerin, each one ounce, ferric chloride, 15 grains, and water, two ounces, make a good spray.

The general treatment demands absolute rest in bed and light purgation followed by stimulation, especially circulatory, to keep up the failing strength. Special attention must be paid to keeping up nutrition. The ingestion of large quantities of physiological salt solution is desirable to help the naturally increased diaphoresis and stimulate diuresis for the purpose of washing out the toxins. Small doses of salol (gr. iii), calomel (gr. 1/8) and sodium bicarbonate (gr. x.) tend to keep the alimentary canal in good order.

General anodynes and hypnotics are to be chosen with care to avoid the weakening of the heart's action. Dover's powder or codein seems to be satisfactory. Trional can be used with care. The pains may be greatly relieved by the application of heat or counter-irritation.

Treatment of Complications.—The nasal occlusion is best managed with a 2 per cent. cocaine spray followed by adrenal powder and an alkaline aromatic spray.

Treatment of Sinus Complications.—We will consider the non-operative treatment for the sinus complications along medical lines. The sinus complications are treated by keeping the nose free by the method already described. If that is not sufficient, the hot nasal douche should be used; take two quarts of salt solution as hot as can be borne with half an ounce of sodium bicarbonate, and use a fountain syringe at an elevation of six inches, allowing the solution to run into one nostril and out the other, slowly. The patient should hold the head over a basin. If the ethmoid cells are involved, the head

should be bent down to raise the water level in the nose to cover the ethmoids. If the sphenoids are invaded, the head should be depressed as much as possible on the sternum and the back bent forward. The mouth must be kept open and the patient should breathe through it. Avoid backing up of the water; keep the outlet free lest the water be driven into non-infected sinuses, or the ears and infect them. After the douche use some aromatic spray.

The surgical treatment for the air sinuses is removal of nasal irregularities and hypertrophies interfering with natural drainage, which together with the hot douche will usually relieve the severe pain. We have not the space to consider further the more radical surgical treatment.

The tonsillar condition can be treated by strong applications of nitrate of silver up to 15 per cent. or by hydrogen peroxide gargle or spray preceded by a hot water gargling. If there is an accumulation of pus, an incision is indicated to evacuate it.

Surgical interference in case of obstructed larynx is tracheotomy or scarification, and intubation, in rare cases.

Summary.—Influenza is infectious. The bacillus enters through the mucous membrane of the pharynx. The diagnosis is readily made in the great majority of cases as soon as symptoms appear. It is amenable to appropriate treatment. The complications of the upper air tract can be avoided by prophylactic care of the nose, or serious results can be prevented by early operation, after infection has taken place.

57 West Fifty-third Street.

DUCHENNE OF BOULOGNE.

A BIOGRAPHY AND AN APPRECIATION.

By JOSEPH COLLINS, M.D.,

NEW YORK.

There is scarcely a physician of similar renown in the annals of modern medicine of whom there is so little known as Duchenne of Boulogne. For some years I have been gathering material relative to his life and searching for a portrait or photograph of him. The former has been obtained slowly, much of it by word of mouth from those who knew him, and the latter from his grand-nephew, with whom I was so fortunate as to become acquainted in Boulogne last summer. A résumé of this material should be interesting, for time has put the seal of immortality upon the name of Duchenne. In medical annals, Boulogne is a city of the East. Its most distinguished physician found one branch of medical science, disorders of the nervous system, a sprawling infant of unknown parentage which he succored to a lusty youth. He accomplished this task apparently without aid of fortune or favored feature, in the face of obstacles that would to-day be unsurmountable. He did not go forth to the world a favored being, knowing no desire that Genius did not hallow. On the contrary, the son of a father who followed the sea, he was in feature and in figure, in speech and in manner, a replica of the common people from whom he had descended. When he left his native city and went to Paris to do the work that is a monument to his industry, an earnest of his enthusiasm, and a testimony to his tact, he had already made serious inroad into the period of time allotted to us in which to do creative work. He was thirty-six and he had practised his profession without distinction for eleven years. He went to Paris to live in 1842, and there he worked apparently without cessation for thirty years.

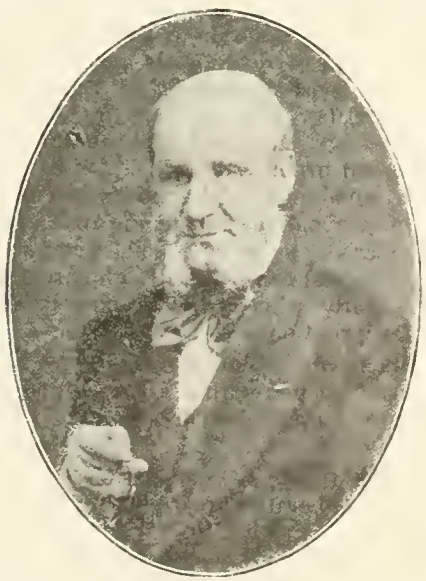

Fig. 1.—Portrait of Duchenne taken about 1866.

There is nothing in Duchenne's early life, so far as I have been able to learn, that would seem to indicate that Wordsworth had him in mind when he said the child is father of the man. His childhood, youth, and early manhood seem to have been singularly uneventful. William-Benjamin-Amant Duchenne was born on the 18th of November, 1806, at 89 rue Neuve Chaussée (now rue Thiers), Boulogne, the second of four sons of Jean Duchenne and his wife, Denise Lasalle. He studied at a college founded by his cousin, Monsignor Haffreinque, and passed his baccalaureate at Douai in 1829, he being then 19 years old. In school he showed an inclination and aptitude for the natural sciences, and the captivation that they had for him led him to study medicine instead of following the sea, which was his father's desire. When he entered the medical school of the University of Paris, Laennec, Dupuytren, Majendie, Velpeau, Cruveilhier, and others whose names have become very familiar to the medical world, were teaching there. Duchenne here formed a habit, which lasted to the end of his days; that of putting into written words everything which he heard, thought, or saw that he wished to remember. It is related of him that he had great repugnance to practical work in anatomy, but as a matter of fact very little is known of his student days. He graduated in April, 1831, the subject of his thesis being "Essay on Burns," and at once returned to Boulogne and in December of the same year he married Barbe Boutroy of Boulogne, who died two years later, leaving one son, William-Maxime-Emile. He is said to have acquired a desirable clientèle, but the death of his wife, to whom he seems to have been ideally devoted, the separation from his son, who was brought up by his maternal grandmother, and the fact that some of his confrères were openly hostile to him determined him to go to Paris, particularly, as he was encouraged by his former schoolmate and friend, Dr. Charles Gros, who had assisted him in the treatment of certain diseases by electropuncture, a procedure suggested by Majendie and Sarlandières, and which now began to interest and absorb him. Meanwhile he had married his cousin, Honorine-Robertine Cornu, a widow. From this union such happiness as he had experienced on his first marriage did not flow.

After taking up his residence in Paris he began

to subscribe himself Duchenne de Boulogne, that he should not be confounded with Duchesne of Paris, and it is this designation that has taken its place in literature. And now began the display of those possessions or qualities of character, industry, poise, and self-confidence which made for his success.

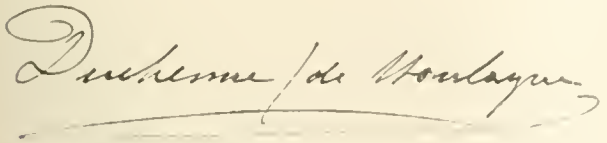

Fig. 2.—Signature in a presentation copy of one of his books.

Apparently it was not appreciated by those among whom he worked in the almshouses and hospitals of Paris that he was booking a box-seat in the coach going to Posterity. Indeed, he was during his entire life without honor in his own country. A few of the mighty in medicine of that day recognized the merit of his work, notably Trousseau, who in his voluminous writings gave circulation to some of Duchenne's discoveries. Besides an appreciation of his merits, Trousseau had also a real fondness for Duchenne. Anecdotes that are still recounted testify to this. Duchenne was not eloquent, and his natural timidity prevented him from expressing adequately and convincingly his thought. Trousseau would often take the word from him, as it were, and with incomparable verbal facility portray the ideas to which Duchenne had been trying to give expression. The latter, recognizing them as his own, would glow with satisfaction and pride to see them appear in the brilliant light which this almost unique clinician, this combination of strong, clear, cool head and warm heart radiated about him. But by the majority of those in whose hospital wards he worked he was looked upon as a poacher in the open or as errant and bizarre. His industry, his perseverance, his sagacity, his frank disregard of conventionality, his unfamiliarity with discouragement, his insensitiveness to the slights of those who hadn't time, finally won out for him in the arena that was open to him, viz., the *Revue Médicale* and the Foreign Medical Societies, in which he ardently sought, and apparently always obtained, corresponding membership.

In Paris he lived at 21 Boulevard des Italiens, where, with the assistance of his servant Alexis and Dr. Chrysaphis, he treated many patients by electricity, meanwhile studying the immediate and remote results of its application. His clientèle was mainly poor persons, but later it must have been of a more lucrative class for some years before his death, *i.e.* at the outbreak of the Franco-Prussian war, he was in the possession of a competency.

He regulated his mode of life so that nothing should interfere with his study. Every morning he went as a visitor to one or two hospitals, chose the most favorable cases for study, and devoted his time to them. The afternoon he devoted to experiments with electricity and photography, both of which were then in their infancy. In many instances he pursued the investigation of a case for years, following the patient from hospital to hospital. The large public hospitals of Paris to-day are, in their arrangement and equipment, far behind the hospitals of most highly prosperous civilized countries. What they were three generations ago we do not have to conjecture, for there is no dearth of testimony to prove that a large part of the clinical material, especially in the big hospitals devoted to the treatment of chronic diseases of the nervous system, like the Salpêtrière, Bicêtre, Hotel Dieu, etc., was not classified or interpreted. Patients were rarely examined fundamentally, and clinical histories, as the designation is understood to-day, were unknown. All motor incompetencies were classified as "paralysis" and functional and organic diseases were almost hopelessly jumbled. The physician or physicians in charge of these hospitals were monarchs of all they surveyed, and their assistants were little monarchs, especially when the big monarch was away. It was a difficult task that Duchenne set himself to interpret to these men disease manifest in patients under their care, and particularly as his aid was unsolicited. Indeed, in many instances he was laughed at by the chief, tolerated by the subordinates, and looked down upon by all. Of course, all this was changed as soon as he began to publish those articles that have since immortalized his name. But it is evident that it often required a combination of tact and insensitiveness vouchsafed to but few successfully to calm the turmoil which his acts often engendered. It is scarcely contributory to the *amour propre* of the physician who says that a patient is bedridden from paralysis to find this patient a few days later not only standing, but carrying a full-grown man upon his back, in order that the observer, and anyone else who will take the trouble to look, may be convinced that there is no real paralysis, especially if the one who instigates the demonstration is an interloper, and really has no right, and scarcely a welcome, in the place! But Duchenne stuck to his task, explaining to anyone who would listen, and arguing with anyone who would deign.

His method of obtaining clinical material accounts, in a measure, for the numerous disputes in which he became involved, as to the priority of some of his discoveries. He was not a pugnacious individual, but he didn't lack opponents, and enemies who looked upon him as a therapeutic specialist, and not a scientist, and who did not hesitate to say so in language more plain than convincing. But the fruit of his labors he submitted with confidence to the medical profession at home and abroad who, not distracted by the sight of the travail or prejudiced by the aggressiveness of the creator, sat in calm judgment upon it and bestowed praise whenever it was merited and gave credit whenever it was due. Indeed, there is much in Duchenne that reminds of Plato. The self-belief, the equanimity, the desire to abide by the collective judgment of his fellow men, the willingness to argue his contention with every comer, and his abiding faith in his own observations and deductions, all suggest the immortal Æginian.

Apparently it was his interest in electricity which first led him to the study of nervous diseases, and although electricity has not justified any of the high hopes that he had of it therapeutically, he really laid the foundation for much of the work which was afterward done by such investigators as Erb. Convinced as he was of the necessity of taking the muscular system for the basis of his scientific investigations with electricity, Duchenne prepared a series of works on the physiology and anatomy of the muscular apparatus. Before his work the physiological function of isolated muscles, the coordination and synergetic effect of their contractions, the relative part that each muscle played in movements of various kinds and of different parts such as the extremities, the trunk and the face, were known vaguely and imperfectly. He classified, defined, and formulated our knowledge concerning them.

Duchenne was struck with the fact that if one placed two poles or electrodes which had been properly wet on moist skin, the current traversed the skin without exciting any appreciable cutaneous sensibility, but localized its action on the muscles or the nerve subjacent. His first publication, entitled "The Art of Limiting the Electrical Excitation in the Organs Without Pricking and Incising the Skin; a New Method of Electrization with Equal Localized Electrization," was published in Comptes Rendus de l'Académie des Sciences, 1847. In 1851, in his communication to the Academy of Medicine, he presented his first observation on the muscles of the face, but it was not until eleven years later, in 1862, that he published his first essay on this subject. This was a veritable storehouse of accurate information. Many articles had been written by philosophers, physiologists, and physiognomists, but only Lebrun had pointed out the resemblance of certain types of human physiognomy to that of animals. Leonardo da Vinci, Camper, Gratiolet, *et al.*, had left some ingenious observations, perhaps even formulated them for utilization in art, and likewise some rules, but these were purely empirical, the results of observation, incomplete, incoordinate, unscientific. But here were the results of experimentation, and results that could be demonstrated by anyone! He was struck with the insight revealed by a statement of Buffon: "When the soul is agitated the human face becomes a living picture, which portrays the passings with as much delicacy as energy, where each movement of the soul is expressed by a line, each action by a character of which the prompt and living expression precedes volition, and reveals by pathetic signs images of our most secret agitations," and he added: "The soul is therefore the source of all expression—it is this which puts in play and causes them to engrave upon the face in characteristic marks the history of our passions. Therefore, the laws that govern the expression of human physiognomy may be sought in the study of muscular action." From this standpoint he approached the mechanism of the human physiognomy, and the results of his labors in this field have furnished sculptors and anatomists, physicians and psychologists, with much reliable information.

His advent into the field of neurology was the study of traumatic lesion of mixed nerves. In the symptomatology of paralysis of the facial nerve, which had been so admirably described by Bell, he made a contribution which, though small, was of great importance. In certain cases of facial paralysis there exists epiphora which is absent in other cases. When it exists, Horner's muscle is paralyzed, and it no longer plunges the lacrymal point into the lacrymal sac, while, when it is not involved, these little muscular fascicles preserve their contractility. It is claimed by those who should know that this work alone would give Duchenne high rank as a scientific investigator. He also pointed out that in facial paralysis of cerebral origin the electrical contractility of the paralyzed muscles is intact. In symptomatic facial paralysis, due to a lesion of the cerebral peduncles or to any lesion as high as the protuberance, and alternating with paralysis of the members of the other side, there exists in the face abolition of the electrical contractility of the paralyzed muscles, while the paralyzed members of the opposite side preserve their normal electrical irritability. In facial paralysis dependent upon an organic lesion of the nerve at the point of its emergence from the oblongata, the paralyzed muscles lose their electrical contractility. Finally, he pointed out that in rheumatic facial paralysis it is necessary to distinguish two varieties, one in which the electrical contractility of the muscles is scarcely diminished, the other in which the electrical contractility is profoundly affected or abolished, and he pointed out that when this occurs the lesion is severe and the paralysis rebellious, often incurable. This is the basis of sound teaching as to prognosis in this disorder at the present day.

Practically all that is known concerning the familiar forms of lead palsy and the electrical reactions in this condition were established by him. But this was of small importance compared with his investigations of the diseases of the spinal cord.

Until he studied the subject of the disease that is now known as anterior poliomyelitis, there was still much discussion as to the anatomical lesion upon which it was dependent. Heine had spoken in favor of its dependency upon a spinal lesion, but most writers insisted that it was an "essential paralysis." The atrophy which almost invariably occurs in the paralyzed limbs was attributed to inaction, but Duchenne maintained that it required more than the absence of movement to produce such profound disorder of nutrition of muscles, bones, and ligaments, and that it was necessary to seek for a lesion much more fundamental. He compared the evolution of the clinical picture in anterior poliomyelitis with that resulting from traumatic lesions of the spinal cord in the adult, and in 1855 he formulated the hypothesis that the lesion was in the anterior gray matter of the spinal cord. Ten years later Charcot and Cornil, Prevost, and Vulpian, not to mention others, substantiated this claim. Later he described anterior poliomyelitis of the adult, a disorder similar to that of the atrophic paralysis of children, and stated that the atrophy of the ganglion cells of the anterior horns was very probably the principal anatomical lesion of this variety of acute spinal paralysis of adults.

He was not so successful in splitting up the remaining cases of paralysis of the extremities attended with atrophy resembling these cases that we have been describing, and from which has since been distinguished polyneuritis, Landry's paralysis, and certain forms of diffuse myelitis, although he had, as I have said, distinguished three distinct species of paralysis dependent upon atrophy of the cells of the anterior horn, *i.e.* so-called infantile paralysis, and subacute poliomyelitis in children and poliomyelitis of the adult.

But it was in the field of the amyotrophies that his labor was most productive. He did something for the subject of electrodiagnosis and electrotherapeutics, and he did much for the artist who seeks to interpret the anatomy of expression, but in the field of amyotrophies he made contributions which were fundamental and which will always remain as landmarks.

The disease above all others of the spinal cord that is associated with Duchenne's name is spinal progressive muscular atrophy. Observations of this disease were apparently made fairly early by him, soon after he came to Paris. But it was not until Aran, then physician to the Hôpital Saint-Antoine, published Duchenne's cases that knowledge of the disease became at all disseminated among the profession. Aran's chief work on the subject was published in 1850, and there can be little doubt that it was chiefly a summary of Duchenne's observations, as testify the following words of Aran, "I owe a thousand thanks to Duchenne of Boulogne,

who has put at my disposal all the facts which he has gathered, and without whose aid I should not have been able to give all the details of the muscular system in my cases." In the beginning Duchenne seemed to incline to the view that in this form of disease there was a primitive muscular alteration, but he soon contended that the lesion was of the anterior horn cells of the spinal cord. Apparently he never interpreted the class of disease that is now known as the dystrophies, although he remarked most of the distinguishing features of them, such as the appearance first of the atrophy in the muscles of the face, the family character of the disease, the apparent hypertrophy, etc. In fact, the latter feature, viz., the pseudohypertrophy, was described by Duchenne with a great deal of detail. It is remarkable that Duchenne, having made the masterful study of the disease which is known by his name, was so willing to bend the knee to the pathologists who maintained that the disease was not in reality one of the spinal cord which Duchenne at first contended it was. He returned to the belief, apparently, that it was one of primitive atrophy of the muscle, but the difficulty of reconciling the absence of lesion in the spinal cord in many of the cases of chronic progressive muscular atrophy that came to autopsy was the chief reason for this turning about of Duchenne. Finally, as it became evident that there were many different forms of atrophy, it was realized that the form described by Duchenne had a definite clinical course and a definite pathological foundation. After the establishment of this disease, the description of bulbar palsy, or of glossolabial paralysis, as he called it, was easy. To this disease he gave a clinical description that has never been improved. He recognized, moreover, that it was in reality a disease similar to that of spinal progressive muscular atrophy.

The part that he had in the interpretation of locomotor ataxia was that of an original observer, despite the fact that it was recognized as a definite disease in England by Stanley, and by Todd, and in Germany by Romberg, it seems justifiable to assume that Duchenne knew nothing of the work of these investigators. Although his descriptions of this disease do not tally so accurately with its present-day delineation, as do those of some of the other diseases that he described, this is due to the fact that tabes does not display itself to-day as it did half a century and more ago. He separated it from the paralyses; he recognized its luetic parentage, and he depicted the morbid alteration of the cord upon which it is dependent. Like so much of his purely clinical work, his investigations of locomotor ataxia were disseminated largely through the writings and teachings of his brilliant contemporary, Trousseau. This by no means exhausts the enumeration of his works, but they represent his chief contributions.

On the 27th of June, 1807, a monument to his memory was unveiled in the Hospital of the Salpétrière. In the half century that had elapsed since he began those investigations in the wards of that hospital, his fame had grown to such an extent that he deserved the eulogiums that were pronounced upon him by Joffroy, Raymond, Lereboullet, Duval, and Motet. It bears the inscription

1806-1875

A. Duchenne (de Boulogne)

Electrisation localisée

Physiologie des mouvements Neuropathologie.

Mathias Duval said at the time that Duchenne's work consisted essentially in bringing order out of confusion, especially in the realm of the nervous and muscular systems, in unraveling the physiology of movement, the mechanism of the human physiognomy, and in the application of electricity, and perhaps this adequately summarizes it.

Not only was he a clinician in the literary sense of the term, *i.e.* an interpreter of disease phenomena at the bedside, but he was highly skilled in the art of prognosis—perhaps the most superior quality of the physician. Overshadowed by Charcot and Trousseau, he measures well up with these giants of medicine a generation after their death, and the years to come may add such to his reputation that he will be counted the chief exponent of clinical

Fig. 3.—Frontispiece to the Album de Photographies Pathologiques, showing Duchenne demonstrating faradization of the temporal m

neurology in the relation to pathology of his time.

The penalty paid for greatness is manifest often by an abiotrophy of the germ plasm. The man or woman who writes his or her name in capital letters on the scroll of time often pays by the forfeiture of his or her kind. Duchenne had one son who studied medicine, graduated, and entered practice, but who succumbed to dementia præcox when he was twenty-five years old. To this son he was devotedly attached, and although Duchenne saw very little of him until his maturity, the young woman who became his wife proved a veritable daughter to Duchenne for the remainder of his days. Her kindly assistance and sympathy were often mentioned by him, and the name of Mlle. Julie Bonnel is a cherished one with the Duchenne descendants.

The accompanying reproductions of photographs

give some idea of Duchenne's personal appearance in the latter years of his life, but they tell little of his youth and of his appearance in the struggling days. He was a son of the vigorous race of Boulognese, for there is a clear record of his forbears for two hundred years in Boulogne, and the best of them were like his father, seafaring men. He was of medium height and build, with deep chest and broad shoulders, pronounced facial features, and of a color and carriage that bespoke physical vitality, the pictures of him demonstrating the contraction of the frontal muscle reproduced here shows these features admirably. With these he combined the moral qualities of perseverance, endurance, and self-reliance, which are the possession of so many obscure heroes of the sea for whom the accomplishment of duty is adequate reward. In his youth he was all ardor, enthusiasm, and maintained that "Still waters" had no appeal to him, and that one may expect nothing remarkable from one who knew not how to be young. Frank, he did not attempt to conceal his opinions because they might displease. This gave his manner, particularly in the later times, the appearance of brusqueness. He was independent, expansive, ardent, tenacious. These were his dominant racial qualities, and they were the foundation of his whole career. He was not easily discouraged, and pursued his researches and experiments with a patience and perseverance unbounded.

In 1855, when he published his work on "Localized Electrization," he remarked that his task was far from finished, and that it remained for him to study well the muscular functions with the aid of clinical observation, and he added: "Will my life suffice? I trust so by the aid of God—and my confrères." Ten years sufficed for this labor. When he was old the suggestion of honors rather than the offer came to him. Dumas urged him to offer himself as member of the Institute. He is said to have replied: "No, my only ambition is that I shall not die, living always in my works. There are those who have all honors to-day, but later they will be forgotten, while my work will still live." No lack of self-belief or self-reliance in these words!

Duchenne is said to have had a character of great joviality, loved jokes, and was delighted when they succeeded, but in later life the world seemed a very serious place as he became more drawn into the maelstrom of work. It is related of him that he was often so occupied and preoccupied that he forgot his appointments, even written ones. Invited once to dinner at Baron Hausemann's, Prefect of the Seine at that time, he presented himself in evening dress eight days after the event, and it was with great difficulty that he was made to understand that the dinner had taken place the week before.

The siege of Paris was a trying time for him. His ancestors were many of them combatants, and his blood, though moving slowly from the burden of years, called him to the defense of his country—a call to which he could not respond. He found consolation in succoring the sick, the wounded, and starving during that terrible time. In one year, 1870-71, he lost his wife, his brother, his son, and a number of other near relatives. To Duchenne, who was always a man of strong family feeling, especially in his late maturity, this was a most depressing period, and it apparently initiated the symptoms of cerebral arteriosclerosis from which he died four years later, and which caused him and his friends, because of the distressing character of the symptoms, so much pain and misery meanwhile. In 1875, on his return from a trip to London, he was seized by an attack of cerebral hemorrhage, and succumbed to the disease that sufficed for his father fifty years earlier.

Although brought up to conform to the robust faith of his fathers, he had, like so many other scientific men of his period, ceased to be a participant at public worship, but when he was seized with fatal illness he not only sought the mediation of the church and its ministers, but he charged his friend and confrère, Dr. Gros, not to omit calling attention to the fact that he had received the last sacraments. His last words are said to have been "Plus j'approfondissais la science plus je reconnaissais l'existence de Dieu."

In giving an account of his funeral, a paper of the period said: "We will not describe the ceremony. The least known and least important member of society could not have had a more insignificant funeral procession." As a matter of fact, scarcely a score of friends accompanied the body to the grave. His modest tomb is in the cemetery de l'Est at Boulogne, near that of his first wife, and is nearly hidden by the weeds and thorns of time. It bears the simple epitaph:

To the memory
of
Dr. William Duchenne of Boulogne
died at Paris, 17th September, 1875
at the age of 69 years.

RELATION OF ACCIDENTS TO FUNCTIONAL NERVOUS DISEASES AND PSYCHOSES: MEDICOLEGAL CONSIDERATIONS.*

By ALFRED GORDON, M.D.,

PHILADELPHIA, PA.

ASSOCIATE IN NERVOUS AND MENTAL DISEASES, JEFFERSON MEDICAL COLLEGE, EXAMINER OF THE INSANE AT PHILADELPHIA HOSPITAL.

THE modern requirements in every sphere of human activities are highly contributory to accidental injuries. Traumata may lead to surgical and nervous disturbances. As we will be concerned to-night exclusively with the latter, it is necessary first to emphasize what factors are the most frequent causes of this disorder.

Speaking only from the standpoint of personal experience (which incidentally is quite extensive), I may say that, among all accidents, those caused by conveyances (railroads or trolley cars) give the largest contingent of victims. Laying aside the organic injuries, such as fracture or dislocation of the vertebræ, tearing of the spinal cord or of peripheral nerves, fracture of the skull, followed by tearing of or hemorrhages in the cerebral tissue, I will confine myself to functional nervous disorders. The subject is an extremely important one for two reasons: *First*, traumatic functional neuroses are exceedingly frequent; *Second*, the neuroses are very frequently misunderstood, and therefore a proper estimate of their value is not always given.

The functional nervous diseases produced or perhaps brought out by such accidents are: hysteria, neurasthenia, chorea, paralysis agitans, amnesia. A review of the clinical pictures is necessary for a proper appreciation of the medicolegal questions. Let me therefore emphasize as briefly as possible

*Read by invitation before the Camden City Medical Society, December 3, 1907.

the essential features of each of these affections, omitting the details.

Hysteria.—When a collision, for example, occurs, the shock and the fright into which the passenger is thrown are sufficient causes to disturb the workings of the entire central nervous system or of its main centers. Supposing he or she during that time is thrown even not violently against the seat of the car, the anticipation alone of a possible severe injury or of a fatal injury, or else of immediate death, is capable of putting out of order the function of the nervous system. During the first few days, or even weeks, the patient still dreads that his life is in danger. The essential features of hysteria are:

Sensory Symptoms.—Hyperesthesia in areas or along the spine; loss of sensations in the distant segments of the limbs (glove-like and stocking-like anesthesia); anesthesia confined to an entire half of the body (hemianesthesia); anesthesia of the pharynx, of the conjunctivæ, of the retina. The latter will be manifested by a contraction of the visual field. The special senses may also be affected. Sudden partial blindness or deafness (without material changes in the eyes or ears), vomiting occurring immediately after the accident and continuing for several days or weeks without any relation to the food and with an excellent appetite—all these symptoms occur quite frequently.

Motor Symptoms.—Palsies, contractures confined to segments of limbs are not infrequent, but they are never accompanied by disturbances of reflexes usually seen in organic nervous diseases. The absence or exaggeration of knee-jerks, toe phenomena, muscular atrophies with reactions of degeneration accompany organic but not hysterical palsies.

The function of the viscera may also be disturbed. Hysterical aphonia, anuria, polyuria, retention of urine are well known phenomena. I refer you to a very interesting case published by me in the Medical Record, August, 1900, of a woman who became anuric after an emotion.

Psychic symptoms are quite frequent. Temporary amnesia, capriciousness, inconsistencies in the ideas and conduct, dissociation of personality, hallucinations are possible occurrences in hysteria. Hysterical subjects are easily influenced to change their thoughts, to do certain acts, to acquire certain sensations, to execute or to adopt certain motor phenomena. Suggestion or autosuggestion plays an enormous rôle. I have also seen cases of hysterical paroxysms following railroad accidents. A young girl of seventeen, while lying in bed, contorted herself, assumed the position of opisthotonos, was animated with a generalized tremor, so that she was unable to utter a word distinctly.

These are the characteristic manifestations in the motor, sensory, and psychic spheres of a hysterical individual. Of course, not all of them are simultaneously found in every case, but when some symptoms are present in the form and intensity as described above, the diagnosis of hysteria can be made without hesitation. Intentionally I omitted details, as the latter may be encountered in other affections.

Neurasthenia.—This neurosis frequently follows accidents. Its main features are: physical exhaustion and undue irritability, so that the patient cannot stand the least contradiction or annoyance. The neurasthenic feels fatigue upon the least exhaustion. Mental processes are also sluggish: the least mental effort disables him from continuing his work. The patient complains also of backache, headache, and insomnia. The symptoms are mainly subjective. The objective symptoms are very few: tremor of the hands, decreased reflexes, cold, clammy skin, and the special facies. The latter is that of a tired and depressed individual and one full of anxiety.

Chorea, with its irregular and incoherent muscular movements rapidly following one another, is too well known to dwell upon. It does not frequently follow accidents. Within the last three years I have seen only two cases, and then there was a history of previous attacks. The shock of the collision was immediately followed by a new attack of chorea.

The same remarks can be made about *Paralysis agitans.* In one case of a middle-aged woman the onset of the shaking palsy was traced to twenty-four hours after a trolley accident. In two other cases (a man and a woman) the shock of the accident was the direct cause of aggravation of the previously existing symptoms, which from that time kept on increasing in intensity. As it is well known, the disease is characterized by a continuous tremor affecting mainly one or both hands when the latter are at rest, and by a fixed attitude of the body, mask-like expression of the face.

Amnesia.—This term is applied in practice to an acquired diminution or loss of memory. There are two classes of amnesias: functional and organic. The characteristic feature of organic amnesia consists of its permanency and progressive evolution. Here, by virtue of an organic alteration of nervous elements, the memory for recent events is first affected, as new impressions can no more be associated and preserved. Then gradually old intellectual acquisitions become effaced.

Functional amnesia presents by far more variations than organic. It may concern only a certain group of ideas; it may be general, in which all past events are lost; it may be partial, as in cases of double personality, a striking example of which was reported by me in the *American Journal of the Medical Sciences*, 1906; it may be localized when it concerns only a certain principal fact of life. Sometimes, in addition to the latter, a certain period of time immediately preceding it is forgotten. We then speak of retrograde amnesia. When the period of time following the principal event is forgotten, there is an anterograde amnesia. These two forms may be combined. Within the last three years I have seen two cases of retroanterograde amnesia which followed a fall from a trolley car in which the patients struck their heads against the ground. In one of them there was loss of consciousness; the patients were confused for only ten minutes. A careful examination revealed in both cases no symptoms of an organic lesion. Subsequent events showed the diagnosis in both cases to be correct, as the patients made an uneventful recovery.

Medicolegal Considerations.—In the presence of an individual who, having sustained a trauma, complains of disturbances of a nervous or psychic order, the following medical problems must be solved: *First*, is the alleged disorder genuine or simulated, and what is its nature? *Second*, should the symptoms observed be attributed to the traumatism? *Third*, if the latter is correct, what is the degree of incapacity for work, what are the prognosis, duration, and termination of the malady?

1. The determination of simulation is as a rule not difficult. When an affection is characterized by objective signs, they will be easily recognized. It is absolutely impossible for anyone to simulate an anesthetic pharynx, an anesthetic conjunctiva, a contraction of the visual field, a genuine hemianesthesia, a genuine plus reflex. The ensemble of these stigmata constitutes the typical picture of

hysteria. This malady is a well-defined morbid entity, which, except in rare cases, cannot be confounded with any other nervous affection. It is true that an hysterical paroxysm with its screaming, laughing, and various motor and psychic phenomena, can be to a certain extent simulated, but an experienced physician, familiar with the disease, will have no difficulty in recognizing it. The psychic symptoms of hysteria are not ordinary symptoms; they present a special physiognomy, the main points of which can never be guessed by the simulator. It is the entire picture of the attack that should be taken into consideration, not individual elements.

To illustrate to what errors a nonfamiliarity with the disease may lead, I will cite you a case in point. An attorney requested me to examine one of his clients, who claimed to have developed a hemiplegia after a broken trolley wire struck him. The physician in charge pronounced it an apoplectic stroke (there was a partial loss of consciousness) caused by the electrical current of the wire. The patient presented a limping of his left leg and some inability to use the left arm. The condition persisted almost two months. Examination showed a state of affairs totally different from typical hemiplegia which is due to a brain lesion. The knee-jerk was not exaggerated, and the abnormal reflexes usually found in such cases were absent. The entire left side was also wholly anesthetic. It was unquestionably a case of hysteria. The attorney, of course, did not like my diagnosis. I learned later that he settled the case out of court, and the patient made a complete recovery shortly after he got his money. In fact, I cured him with a few séances of a strong suggestive static breeze.

A woman was in a slight railroad accident. She was only thrown on the floor of the car and there was no surgical injury. When picked up she could not hold herself in an erect position nor could she walk. The legs gave way under her. The condition was pronounced grave and a diagnosis of complete paraplegia due to a hemorrhage in the cord was made. I saw the patient since then on several occasions. There was no paralysis, as she could move the limbs easily while in bed, but could not use them when standing or walking. The reflexes were normal, sensations normal, and the sphincters intact. It was a case of hysterical astasia-abasia, from which she fully recovered after a course of rest treatment with good feeding. The claim made in court was a large verdict for a permanent and incurable spinal cord injury. Of course, I was not called to the stand because of my diagnosis. A large verdict was obtained, but injustice was done to the railroad company. My diagnosis was certainly correct.

Far more difficulty is encountered in the medicolegal consideration of *neurasthenia*. This malady is characterized almost exclusively by subjective manifestations. When a patient, having met with an accident, complains of fatigue, backache, headache, insomnia, and irritability, there are no means of verifying the presence or absence of each of these symptoms.

Nevertheless, when the disease is pronounced, the general aspect of the individual will aid in forming an opinion as to the veracity of his complaints. There is usually loss in weight, loss in strength, pallor of the face, depression, cold and clammy skin, tremor. When the case is mild, the latter symptoms are absent, and then one has to rely upon the first series of subjective disturbances. I have seen time and again that, in spite of an enormous shock following for example a collision or a fall from a height, only a few subjective symptoms would be complained of. In such cases my opinion before the jury and court would be expressed thus: "If the subjective symptoms the plaintiff claims to suffer from are correct, he is neurasthenic; but I have no means to verify them."

In such a manner justice is done to both sides, defendant and plaintiff. My rôle, I believe, is to present medical facts and explain their meaning to a lay jury. The decision as to the relation of these symptoms to the accident is left entirely to the impartial judgment of the twelve men.

In the majority of traumatic cases hysteria and neurasthenia are combined. This facilitates considerably the problem, as objective signs are almost always present, and if there is a certain hesitancy in the mind of the physician in accepting the subjective symptoms, due credit should be given to the objective phenomena of the victim of the accident.

Chorea and *Paralysis agitans* developed after a trauma present no difficulty in being recognized. Simulation in such cases is an impossibility and the objective symptoms are too evident to be contested.

Considerable difficulty will be encountered when amnesia is the only symptom produced by the accident. If the loss of memory is associated with hysteria, the symptoms of the latter will render sufficient aid, but when hysterical stigmata are absent the difficulty becomes very great in deciding the question whether the amnesia is genuine or not. In such cases the examination should be repeated, the individual must be tested with great perseverance and patience, he must be questioned as closely as possible and for a prolonged period of time. Great skill and tact are necessary in investigations of this sort, and in some cases one may arrive at a positive opinion.

2. The second medicolegal problem is, as I said above, to determine whether the maladies discovered in an individual are attributable directly to the accident. While a shock, physical or mental, is a frequent cause of functional nervous diseases, one cannot nevertheless be affirmative in a given case unless the state of health prior to the accident is known to the examiner. Hysteria, neurasthenia, chorea, or paralysis agitans may have existed before the plaintiff sustained the shock. It should, however, not be forgotten that if any of those affections existed before, the newly sustained shock will aggravate it. A person, for example, is supposed to be in the process of recovery from a neurosis. Should he at that time sustain an injury the primary disease is likely to return and present itself in a more pronounced form than in its first attack.

Individual predisposition should also be taken into consideration in giving an account before court and jury. Neuropathic individuals are more apt to suffer from any of these neuroses than normal individuals. They are predisposed, and the least shock disturbs the workings of their nervous system with the greatest facility. Individuals whose vitality, and therefore resisting power, has been lowered following a protracted infectious disease, are inclined to respond with unusual promptness to the effects of a shock. The neuroses will find a fertile soil for their development. It is consequently important to surround one's self with this precaution in giving an estimate of the degree of the individual's suffering.

3. The last proposition of our problem is to determine the degree of incapacity caused by the accident, the consequences, duration, and termination of the latter.

Hysteria and neurasthenia are not synonymous

of simple nervousness, as some pretend. They are well defined diseases of the nervous system. They do incapacitate for mental or physical work, but only to a certain extent. A neurasthenic with his chronic physical and mental fatigue is certainly not able to accomplish much. The disease presents variations in its intensity. If the symptoms are marked, the patient must go to bed, as rest is the most essential element of the treatment. Then there is no question of work. When the case is mild, and the fatigue is not particularly marked, and the backache with the headache only occasionally disturb the patient, a certain amount of work can be done by the patient, and with the proper regulation of the patient's mode of living he can be made to feel quite comfortable.

Hysterical patients are not very much disturbed in their daily life when the psychic symptoms are not present. One may bear the anesthesias, hyperesthesias, and tremor, also contraction of the visual field without being particularly annoyed. But, as a rule, there are psychic phenomena, viz., great emotionality, irritability, crying spells, restlessness, impressionableness, etc. Such patients are unfit for work. Their mental concentration and application are of a very short duration. Whatever they commence, they are unable to finish. Their association of ideas is incomplete because of instability and want of depth of mental processes. For this very reason good work cannot be expected from those in whom psychic disturbances are marked. Even in those cases which are apparently free from mental symptoms, the least emotion or undue exertion will bring forward the above psychic manifestations so characteristic of hysteria, because the nature of the disease predisposes them to an unusual responsiveness. The degree of incapacity will depend upon whether the psychic symptoms are present or not, also upon the intensity of the latter.

Chorea and paralysis agitans incapacitate for physical work considerably, but only partially for mental work.

When amnesia occurs, a disability will ensue if it is of a generalized character. If it concerns only a certain past period of life (retrograde or anterograde form), there is no disability whatever. The individual is perfectly able to earn a living, as the memory is good for all events except that one.

A proper discrimination as to degree of incapacity in all the neuroses is always possible when the above elements are taken into consideration.

Not infrequently we are asked about the future of the victims of accidents. My answer is that while the neuroses are curable affections, they nevertheless may last an indefinite time. The results depend upon many circumstances, viz., treatment, surroundings of the patient, previous general health, ability or inability to carry out certain instructions, outside influences, and finally the individual make-up. In exceptional cases the disease may last for years in spite of treatment. It should not be forgotten that recurrences are possible, and in fact are not infrequent. In the majority of cases the patients make a good recovery. The latter is possible in hysteria, neurasthenia, chorea, and amnesia, but not in paralysis agitans.

Psychoses.—A very important chapter from a medicolegal standpoint is constituted by mental diseases. A shock caused by an accident is likely to produce mental disturbances, but between the latter and distinct, well-defined, mental affections there is a great difference.

Hysteria is, properly speaking, a psychic disturbance, and its mental phenomena described above belong by right to this chapter. They have been sufficiently emphasized at the beginning of my address. Amnesia is another psychic phenomenon. It is also familiar to us.

When the immediate symptoms of brain injury are severe, there is usually a cerebral hemorrhage or fracture of the skull. A cerebral contusion, followed perhaps by minute disseminated hemorrhages, is apt to be followed by mental symptoms, such as vertigo, delirium, confusion, loss of memory, and coma. In such cases the patient either dies or gradually recovers his mental faculties. When, instead of recovery, dementia develops, there is always an underlying basis in the form of alcoholism, syphilis, epilepsy, or arteriosclerosis.

In infancy and childhood the condition is somewhat different. When a child in the process of development undergoes the effect of a severe cerebral injury, the result may be very serious. If epilepsy follows there is no doubt that the mental growth will be interfered with. Faulty cerebral development may follow a grave injury to the head, irrespective of epilepsy. The prognosis, therefore, is guarded when arrest of intellectual development is observed shortly after a cranial injury.

The relation of paresis to traumata is a question of great importance. There are some alienists of note who believe that an injury is apt to develop paresis, others find no relation between the two. Paresis is an incurable disease; it is one of the most serious of mental affections. If its symptoms are noticed first after an accident, one is naturally apt to attribute them to the latter. At the Congress of the French Neurologists and Alienists in 1906 this question was the subject of a special report, so important it was considered. It was discussed at length by the most brilliant minds. It is frequently brought forward as of a special import, as courts and lawyers are waiting for our decision.

My personal views on the subject are that paresis is not and cannot be caused by an accident. It is a mental disease of a slow, but progressive evolution, and characterized pathologically by a gradual degeneration of cerebral tissue. If its symptoms become sometimes conspicuous after a trauma, is it reasonable to suppose that a cerebral degeneration sets in immediately and at once produces the symptoms the development of which require a long period of morbid changes in cortical cells? In my judgment the disease existed before the accident, and the latter served only as an exciting cause for its more rapid development. Medical records are abundant with examples of this nature in other affections.

The mental manifestations of paresis, in its expansive or depressive forms, the physical signs, as irregular and unequal pupils, the disturbance of the pupillary reflexes, characteristic speech, tremor of the tongue and hands, changes in the reflexes (loss or increase), apoplectiform or epileptiform seizures—it is not conceivable that these symptoms will explode shortly after an accident without being in existence prior to the accident. My answer, therefore, in court will be that trauma is not the direct cause of paresis.

I will now cite a case with another mental affection before discussing the latter. The man I was called upon to examine fell off a ladder while working at a building. He struck his head and became unconscious. In the evening of the same day he had an epileptiform seizure with generalized convulsive movements. He was taken away from work, kept at home, and treated for epilepsy. Since then

his mental faculties became obtunded. His memory began to fail. He was unable to give an account of himself. He would make grave mistakes. Would ask for a fork when he wanted a knife; would forget his wife's name. He would try to get in his neighbor's house instead of in his own. He also had outbreaks of extreme furor, in which he would use profane language, and even strike, so that the lives of his relatives became endangered. After the explosion of this passion subsided he had no recollection of what occurred.

When I saw him months later he presented marked tremor of lips, increased reflexes, pronounced confusion, and a vague expression of the eyes with dilated pupils. He could not give me an explanation of those outbreaks of passion, of which he had no recollection. The patient had evidently been suffering from epileptic dementia. The attacks he presented were psychic in form, but of epileptic nature.

The question arose in court whether the trauma was the direct cause of his mental condition. A very careful search into the man's previous life, with data obtained from his wife, who was separated from him before the accident, also from his relatives and friends, revealed the fact that while the man never had a seizure prior to the trauma, and was mentally clear as he worked in the same place for seven years, he neverthless had a syphilitic infection and used alcohol to an unusual excess.

My opinion, based upon all the facts of the case, was formulated as follows: "The trauma was an exciting cause to the epilepsy with its dementia, but the patient was predisposed to the disease. Any other cause would have produced the same condition. It is also possible that the mental affection would have developed without any apparent cause, as chronic alcoholism and syphilis are sufficient etiological factors in epilepsy." The verdict was just, because it was moderate. He was not entitled to a very large compensation, but compensated he should be. An accident may be the exciting cause of a delirium or a delirium tremens in an individual profoundly intoxicated with alcohol. Similarly I have seen a confusional state developed in individuals with a previous alcoholic history. A thorough investigation of the personal antecedents is absolutely indispensable in cases of this category.

Conclusion.—The chief aim of my address was to present to you an impartial view of the medico-legal side of a highly important problem. In cases of railway or other injuries caused by neglect of those who have in charge the management of transportation cars, it is no more than just that the injured person should be compensated for disability. On the other hand simulation or exaggeration of incapacity should be condemned. The physician is indispensable to the law. In the name of justice he must be invariably reserved in his statements. His opinion must be formed after a thorough study of each individual case. He must not forget that, while some severe traumatisms produce mild symptoms, some insignificant traumata cause marked disturbances of the nervous system. The degree of the disability and the prognosis of the affection vary in each individual case. The recognition of the affection, the recognition of the influence of the accident upon its manifestations, finally the discrimination of a genuine malady from a simulated one—all these elements can be acquired only when the physician is properly prepared. In view of the practical importance of the subject, a continuous study of it is indicated.

FETID BREATH ("BROMOPNEA").*

By WILLIAM J. LEDERER, D.D.S.,

NEW YORK.

LECTURER AT THE NEW YORK COLLEGE OF DENTAL AND ORAL SURGERY; DENTAL SURGEON TO THE GERMAN HOSPITAL DISPENSARY AND COUNTRY SANATORIUM OF THE MONTEFIORE HOME.

It is astonishing how many pople in the best walks of life suffer from bad breath without being aware of it, and how frequently this symptom is permitted to remain without attempting to remedy it. Often when advice is sought the patient is given a deodorant wash, advised to seek the services of a dentist or rhinologist, or treated for some gastrointestinal trouble, usually gastric fermentation or constipation. If any or all these measures bring no relief the patient is usually disgusted, leaves "doctoring" alone for a while, and then pays no more attention to this unhappy condition.

The conditions producing this unpleasant symptom are manifold; they may be found in the mouth, nose, pharynx, larynx, or lungs, or may be induced by gastrointestinal disturbances, by pulmonary, renal, or metabolic disease; even nervous disturbances produce this symptom.

Halitosis is the term formerly used to designate this condition alleged to be derived from the Latin *halitus,* breath, and the Greek *nosos,* disease. This term is poor etymologically, as well as clinically, as it is derived from two words from different languages, and, furthermore, all forms of fetid breath are not due to disease. I beg to suggest the term "bromopnea," to express the symptom of fetid breath; this is derived from two Greek words, *bromos,* stench, and *pnoe,* breath.

Bromopnea may have its origin (1) from the mouth, (2) from the respiratory tract, from the nose, nasopharynx, larynx, bronchi, or lungs, (3) from the stomach, (4) from contaminated gases being exhaled during expiration, the gases having become tainted by diseases of metabolism, renal disease, nervous disturbances, constipation, emotion, menstruation, or any condition which will alter the character of the gases entering the lungs through the capillaries of the pulmonary arteries.

All types of the trouble can primarily be divided into two classes, namely (1) one in which the contamination of the breath takes place after the gases enter the lungs, and (2) one in which the contamination of the gases takes place in the system before they enter the lungs. Those in the second class might be designated as suffering from true bromopnea (*Bromopnœa vera*), while the first type of fetid breath might be termed pseudo or false bromopnea (*Bromopnœa nota*). An example of true bromopnea would be the sour-apple odor in the breath of diabetics, while the stench accompanying angina tonsillaris would be an example of pseudo or false bromopnea.

In treating bromopnea all the etiological factors leading to this symptom must be considered. A careful examination of the mouth should be made and the teeth looked after, as carious cavities not only afford lodgment to food residue, which may be responsible for the fetor, but gangrenous pulps are frequently the cause of offensive odors. The teeth, however, are more often considered the cause of bromopnea than they actually deserve to be. The teeth should receive proper treatment at the hands of the dentist, and if they are the cause of the symptom the bromopnea will speedily disappear at the

*Paper read at the meeting of the Tri-professional Medical Society, New York, November 12, 1906.

completion of the dental treatment. If the teeth are in normal condition and properly cleansed, the gums should be carefully examined, as every form of gingivitis is accompanied by a more or less marked fetid breath, whether the inflammation is a simple ulitis or pyorrhea alveolaris. In mild forms of gingivitis chlorate of potassium or thymol and benzoic acid will act very happily.

℞ Thymol 0,25
Ac. benzoic 3,0
Tr. eucalypt. 15,0
Alcoholis 100,0
Ol. menth. pip. 1,0

M. S.—A teaspoonful in a glass of water four times a day as mouth wash (Miller).

If the gums are spongy and there is suppuration, the writer has had very gratifying results with Liq. aluminæ acet., well diluted, as a mouth wash. Permanganate of potassium is useful as a deodorizer, but this gives, of course, only temporary relief. Some recommend chlorine compounds, such as:

℞ Liq. chlori
Mellis .....āā 15,0
Aq. dest. 300,0

M. S.—Use as gargle.

The gingivitis present, however, must be treated and a strict regimen of oral hygiene observed, also the teeth cleansed, and every trace of salivary calculus carefully removed and the oral cavity kept alkaline by the use of bicarbonate of sodium or hydrated magnesia locally. An alkaline saponaceous tooth powder should be employed, one which contains no gritty substances like pumice or acid materials, like salicylic acid. It is difficult to recommend any of the preparations on the market, as no one but the manufacturer knows what they really contain. The writer finds the following very useful:

℞ Saccharini 0,12
Cretæ præcip. pulv. 30,0
Rad. irid. flor. pulv.
Saponis pulv.
Sodii bicarb. .....āā 8,0
Acid borici 4,0
Ol. gaultheriæ.
Ol. menth. pip. .....āā gtt x

Any suppurative condition, as parulis or necrosis of the maxillæ, will give rise to fetor, but these conditions are evident, and are only mentioned for the sake of completeness of the subject.

If any artificial teeth are worn, plates or bridges, stationary or removable, scrupulous cleanliness is necessary to keep the breath pure. It seems superfluous to mention these facts, but the writer has seen a number of cases of foul breath in people with edentulous jaws wearing well-fitting appliances, and the cause of the fetor was not discovered till they were told to remove their artificial teeth and the palatal surface was found covered with a thick, slimy coating of mucus and food residue; they had not taken out the plates for a period ranging from a week to a month, "as they fitted so well and gave no trouble." Sometimes artificial appliances are inserted over old roots, a most abominable practice, as these stumps fill up with food and mucus, producing a terrible stench.

A great deal could be written about inflammatory conditions of the mouth accompanied by bromopnea, as all the various types of stomatitis are productive of fetor; however, the treatment of these conditions, supplemented by mild cathartics, the free ingestion of water, and proper exercise will speedily terminate the disease and its objectionable symptom.

If the mouth does not reveal any condition which can be responsible for the fetor, the anterior and posterior nares, nasopharynx, tonsils, and larynx, as well as the various sinuses, should be examined, since diseases of any of these structures frequently produce bromopnea. Tonsillar crypts filled with secretions, cast-off epithelium, and food residue, should be sought for, as the stagnating materials may give rise to angina tonsillaris, which is accompanied by a most repelling odor. Sometimes inflamed conditions of the mucosa of the upper air passages will produce no other symptom than bromopnea, and here a nasal douche of physiological saline solution will act very beneficially. Indeed, the internal nasal bath, the snuffing up of lukewarm water, so that it runs into the mouth, as an adjunct to the daily toilet, is underestimated as a prophylactic measure. If any of these conditions are recognized, the patient in receiving medical treatment will of course get rid of the accompanying fetor. Sometimes, however, as in angina tonsillaris, the patient has not always acute pain, and the only symptom apparent is the bromopnea; therefore, all these conditions should be borne in mind.

Diseases of the respiratory apparatus often entail fetor, and beside the routine medicinal treatment, the use of a deodorant will be useful to mask the odor till reparative processes set in. Permanganate of potassium is very useful in these conditions. I strongly advise against the use of many of the deodorizing, perfumed troches and lozenges, as their preparation and ingredients are secret, and many of them, if used continually, will induce gastric disturbances. A pleasant deodorizing pellet which, if slowly dissolved in the mouth, will mask bromopnea, is composed of thymol, menthol, eucalyptol, vanillin, and saccharin, of each 0,001. This pellet is used extensively in Europe, but I prefer permanganate of potassium, though its use is not so pleasant.

Frequently gastric disease is accompanied by bromopnea. Hare, in speaking of the symptoms of acute gastric catarrh, says: "The tongue is also somewhat dryer than normal, and the breath slightly foul and hot." In chronic gastritis patients often complain of a stale, foul taste in the mouth (Eichhorst). Chronic gastritis, gastric dilatation, gastric ulcer, hour-glass stomach, are all conditions which are frequently accompanied by fetid breath, either constantly or periodically, especially in the morning. The treatment here, of course, differs with the disease and the removal of the cause will entail a disappearance of the accompanying bad breath. The above-mentioned conditions, accompanied by *fetor ex ore*, are those in which there is an emanation from the gastrointestinal tract or the air passages, and the exhaled air is contaminated in its course from the lungs till it is passed out by nose and mouth; they are all cases of pseudobromopnea. The conditions mentioned hereafter are those which alter the character of the gases (which become exhaled air) before they enter the lungs, constituting cases of true bromopnea.

Any condition which will affect the functions of the glandular system so as to prevent proper elimination of waste material through the ordinary channels, will also produce a change in the character of the gases in the blood entering the lungs, and a con-

tamination of these gases will give them a fetid character. This is true bromopnea. No class of conditions will produce this more frequently than diseases of metabolism and retention of waste material, as in constipation and renal disease. Hare, in speaking of the symptoms of uremia, says: "A very important symptom of uremia is the peculiar odor about the patient, which is quite characteristic, and which may be due in part to urea which is being liberated." The sour-apple breath in diabetes mellitus has been alluded to previously.

Constipation is more frequently the cause of true bromopnea than any other condition; this, in turn, is of course a symptom of some other underlying disorder. Many forms of indigestion entail constipation. When there is constipation present the materials thrown out by the mucous membrane and the undigested foodstuffs accumulate in the intestinal tract. The mass undergoes decomposition, and Nature, in attempting to establish an equilibrium, taxes other excretory glands to their utmost capacity. Not only are the gases entering the lungs abnormal, but other structures undergo pathological changes. The gum tissues become affected and break down more or less, and the result is not only true bromopnea, but that form of gingival inflammation which alone constitutes pyorrhea alveolaris (Riggs' disease). This can also be demonstrated in various cases of metallic poisoning where the gums become inflamed, though the poison has not been introduced per os, as seen in the blue gum line in lead poisoning. In many of these cases of constipation the skin assumes a darker color, showing that Nature is making every effort to rid the system of the obnoxious material. The treatment in these conditions is evident; it consists in the perfect ridding of the system of all matters foreign and objectionable, and the restoration of normal physiological function of the excretory structures, not only by drugs, but by inducing a change of habit as to diet, exercise, sleep, etc.; in other words, in establishing normal, physiological conditions. A point frequently overlooked is the free ingestion of water. Patients as a class drink entirely too little water.

A great deal could be written about the modification of the breath; indeed, there is no doubt that any condition altering the composition of gases of the blood will produce a different exhalation from the lungs than the normally expired air. However, time and space do not permit this, and the mere suggestion that bad breath is less often of strictly oral origin than is assumed is the object of this short paper.

That the breath is modified by altered physiological function is proven by the fact that many women during their menstrual period are subject to bromopnea, which symptom disappears after the period has passed. Often bromopnea exists during emotional or nervous excitation. This can hardly be termed a pathological condition, and still any deviation from the normal physiological equation belongs to the domain of pathology. My attention was first called to this matter when, some time ago, a friend told me he had noticed a peculiar odor in the breath of his partner during sexual intercourse when orgasm occurred. Also that this was only the case in passionate women, and that he did not derive full pleasure from coitus unless this odor was perceptible. I looked up the literature on the breath in emotion, and found Howe speaks of it and quotes the following case: "On the morning of the 23d May, Mrs. R., a lady of 45, was bitten by a pet dog in the arm. She was very much alarmed at the occurrence and fainted. I saw her an hour later, and, while examining the wound, discovered that her breath was very fetid. Having seen her very frequently before, without noticing anything abnormal in the breath, I questioned her concerning it. She stated that she had been in perfect health up to the time of the accident, and that her breath had not been affected before it. . . The suddenness with which the offensive breath develops in some cases may be explained by the fact that unusual nervous excitement induces a greater destruction of tissue than normally obtains, and before the intestinal glands can accommodate themselves to the increased labor, other organs must assist in getting rid of the obnoxious materials."

Bad breath arising from mental emotion is less amenable to treatment than any other variety, because it often depends on the will of the patient whether the cause shall be removed or not. There is no local fault which can be grasped or removed. The treatment should be directed to the general system, *i.e.* the irritating influences must be removed.

Dr. B. Talmey, in his book "Woman," quotes Monin's Précis elémentaire d'hygiène pratique, in which he says: "The woman's respiration at the time of menstruation has the odor of onions (?). Before and after coition the natural odor corporis of the woman is more intense. Two of the author's patients were reported to exhale an odor somewhat resembling that of onions immediately after the orgasm."

In presenting this short paper on fetid breath, the writer does not assume to bring forth anything new, but simply begs to emphasize the fact that systemic disturbances will not always produce general systemic symptoms, and that bromopnea, so frequently treated unsuccessfully as a condition *per se*, and often not treated at all, is frequently the signal of masked systemic disturbances.

FORMS OF TUBERCLE BACILLI WHICH CANNOT BE COLORED BY ZIEHL-NEELSEN STAIN.

By C. A. TREUHOLTZ, M.D.,

CONTRACT SURGEON, U. S. ARMY GENERAL HOSPITAL, FORT BAYARD, N. M.

In an interesting article in the *Beiträge zur Klinik der Tuberculosis,** Much describes a form of tuberculous virus which does not stain by the usual Ziehl-Neelsen method, but can be stained by a modified Gram stain. Another paper by Michaelides,† in the same publication, reaches practically the same conclusions except that the latter claims that there is a third form of tuberculous virus which stains by the Löffler-Giemsa method, but neither by the Ziehl-Neelsen nor the modified Gram.

The work of these observers having been done almost exclusively with tubercle bacilli of the bovine type, the following investigations were undertaken with a view of determining the presence and frequency of this tuberculous virus in connection with the human type of tubercle bacillus. In this work the modified Gram stain as described by Much was used. It had been noticed in previous work that

*Much: Uber die granuläre, nach Ziehl nicht färbbare Form des Tuberkulose-virus, Beiträge zur Klinik der Tuberculose, Bd. 8, H1.

†Michaelides: Uber eine durch die Ziehl-farbung nicht darstellbare Form des Tuberkelbacillus. *Ibid.*

tubercle bacilli were very infrequently found in the spleen of tuberculous guinea-pigs and this organ was especially investigated.

Guinea-pig No. 1.—Killed two months after subcutaneous injection with human sputa. Smears from the ulcer showed tubercle bacilli by Ziehl-Neelsen stain. Gram stain gave negative results for tubercle bacillus.

Smears from the non-caseous lymphatic glands showed tubercle bacilli by Ziehl-Neelsen and Gram stain. Gram stain apparently brought out more tubercle bacilli and also stained many fine and coarse granules. Smears from the tuberculous omentum showed tubercle bacilli by both stains.

Spleen presented a large number of tubercles to the naked eye; smears from this organ stained after Ziehl-Neelsen revealed no tubercle bacilli after prolonged search through many slides. Gram No. 1 and 3 stain showed few tubercle bacilli and many granules. Portions of this spleen were excised with aseptic precautions and incubated four days, smears were then made and stained by Ziehl-Neelsen and revealed a large number of tubercle bacilli; the bacilli were usually single and no clumps of parallels were noticed.

Guinea-pig No. 2.—Infected as number one and presented the same findings except that the incubated spleen was examined on the third day and showed tubercle bacilli by Ziehl-Neelsen method.

Guinea-pig No. 3.—Infected in the same manner. Smears from the ulcer stained by Ziehl-Neelsen method showed few tubercle bacilli. Gram No. 1 and 3 brought out many foreign organisms, but no typical tubercle bacilli. Sections from the tuberculous lung showed many tubercle bacilli by Ziehl-Neelsen and a few by Gram No. 3.

Sections from a non-caseous lympatic gland stained according to Ziehl-Neelsen showed tubercle bacilli. Sections stained by Gram No. 3 also showed tubercle bacilli.

Sections from the spleen stained by Gram No. 3 showed few tubercle bacilli and many granules. Sections stained according to Ziehl-Neelsen, though tubercles were numerous, only one was found to contain tubercle bacilli. Portions of this spleen were incubated and smears made after twenty-four hours, with negative results when stained according to Ziehl-Neelsen; smears stained by Gram No. 1 yielded numerous granules and a few non-typical tubercle bacilli. Smears made after forty-eight hours' incubation showed tubercle bacilli when stained after Ziehl-Neelsen method.

Sections from the tuberculous liver showed tubercle bacilli when stained according to Ziehl-Neelsen. Sections stained by Gram No. 3 showed more numerous tubercle bacilli and few granules.

Case of chronic pulmonary tuberculosis in a human subject.—Section from the lungs stained after Ziehl-Neelsen showed numerous tubercle bacilli and a few red granules. Sections stained by Gram No. 3 also showed numerous bacilli and a much larger number of granules.

Sections from the liver stained according to Ziehl-Neelsen showed an occasional tubercle bacillus situated in gray tubercle; Gram No. 3 presented the same findings.

Sections from the spleen showed numerous tubercles under the two-thirds lens, but only after prolonged search were a few tubercle bacilli demonstrable when stained by Gram No. 3, but numerous granules were present. Sections from the same block failed to show any tubercle bacilli when stained according to Ziehl-Neelsen.

Case of acute miliary extension from an old cavity in a human subject.—Sections through the miliary tubercles in the lung and stained according to Ziehl-Neelsen presented immense numbers of tubercle bacilli and a few red granules. Sections from the same block stained according to Gram No. 3 showed few tubercle bacilli and numerous fine and coarse granules.

Sections from the liver showed a few tubercle bacilli when stained either by Ziehl-Neelsen or Gram No. 3 method.

Sections from the spleen showed a large number of tubercles under two-thirds lens. Careful search through sections stained according to Ziehl-Neelsen revealed only one tubercle containing tubercle bacilli. Sections from the same block stained according to Gram No. 3 showed a moderate number of tubercle bacilli and numerous granules. Pieces of this spleen were incubated for three days, when smears stained according to Ziehl-Neelsen showed numerous tubercle bacilli.

Growing cultures of tubercle bacilli, when stained according to Ziehl-Neelsen, in addition to tubercle bacilli, showed a few granules. Smears from the same culture stained according to Gram No. 3 showed a large number of undoubted granules in addition to the bacilli.

These investigations show that the tuberculous virus frequently exists in some form that cannot be stained by our usual methods and which is capable of rapidly developing into the fully grown tubercle bacillus capable of being stained by the method of Ziehl-Neelsen.

It is hardly possible that the large number of bacilli found after incubating the spleen can be accounted for by rapid division of those that may be present in the tissue, and moreover single bacilli were the rule in the incubated tissue; it was further found that the spleen which had been incubating three weeks did not show any marked increase in the number over that of four days.

In drawing conclusions from the granules found, we are confronted with several sources of error, namely, the possibility of the presence of other Gram staining organisms, precipitated stain, and points of deeply staining chromatin; these errors were excluded as much as possible by cultural experiments and staining of control slides of normal tissue. An interesting point noticed in these investigations was that the Gram staining bacilli showed a much greater frequency of beading than the Ziehl-Neelsen stained bacilli.

These investigations open up an interesting field of work and will probably prove of utility in the study of negative sputa and other tuberculous products where the tubercle baccillus has hitherto been very difficult to find.

Extension of Carcinoma of the Cervix Uteri to the Paravaginal Tissue. Luigi Asseretto describes the examinations made of the tissues removed in twelve operations for carcinoma of the cervix. They were made to ascertain the usual method of propagation of the disease to the vaginal and paravaginal tissues. The author found that it generally occurred by extension of continuity into the submucous tissues of the paravaginal spaces. More rarely there were metastases to more distant parts by way of the lymphatics, or blood-vessels, or along the nerves. In general, the cancer was propagated along the lymphatics toward the vaginal orifice. Propagation by the blood vessels is rare. The author believes that recurrences are due to inoculation by fragments of cancerous tissue left behind after the operation. A practical conclusion is that we should remove all of the vaginal tissue that is possible, together with all the paravaginal connective tissue and fat.—*Annali di Ostetricia e Ginecologia*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

New York, January 11, 1908.

TYPHOID FEVER IN LATER LIFE.

ONE of the alleged compensations of advanced life is that, although the aged are predisposed, by reason of the senile retrograde changes, to certain serious and for the most part irremediable maladies, they are exempt from attacks of the acute infections common in youth. They are commonly believed to be immune against the acute infectious diseases, except those affecting the lower respiratory tract, typhoid fever especially being generally regarded as exceedingly rare in those past fifty. In the Monsall Fever Hospital, for example, during the decade from August 26, 1884, to August 26, 1894, of 1,217 admissions for typhoid fever there were but four of persons over 50 years of age, and in the London Fever Hospital during a period of twenty-three years only 1.4 per cent. of the cases of typhoid fever were in persons over 50. Manges found but 5 per cent. of all the cases reported to the New York City Board of Health in persons over 45 years old. Hamilton, however, who collected the statistics of the Health Departments of Chicago, Boston, and St. Louis, for the years 1897-1901, inclusive, found 369 deaths from typhoid fever of persons over 50 years out of a total of 3,885 at all ages, a percentage of 9.5. Of 829 cases of this disease admitted to the Johns Hopkins Hospital, Osler states that only 12 were in persons over 50, a percentage of 5.66.

In an article in the *American Journal of the Medical Sciences* for October, 1907, Arthur S. Hamilton presents a study of an epidemic of typhoid fever occurring in the Hospital for the Insane at Independence, Ia. There were 188 cases, 27 of which, or 14.3 per cent., were in individuals 50 years of age or over; 1 patient was 65, 2 were 71, and 1 was 78 years old. These figures are of value in showing that typhoid fever may occur in the aging and the aged, but they do not indicate the relative prevalence, since most of the inmates of the hospital were adults, very few being under 20 years of age. Hamilton studied more particularly the male patients living in two wards and two cottages in which the disease was especially prevalent. Of the 318 men in this part of the hospital, 65 contracted typhoid fever; 96 of the inmates were 50 years old or over and among these there were 9 cases of the disease. The average age of those who suffered from typhoid fever was 38.9 years. While unwilling to draw any positive conclusions from this small number of observations the author nevertheless asserts his belief that "the liability to typhoid fever is very little less from 30 to 40 than it is from 20 to 30, and that the liability from 40 to 60 is altogether beyond what one would gather from most statistics." There is a possible fallacy in these figures, however, which would make them inapplicable to the community at large. If the average individual over 50 years of age is immune against typhoid fever, his immunity is to be attributed probably to a previous attack or to a gradual strengthening of the resisting power by the production of antibodies, in consequence of the repeated ingestion of small doses of typhoid bacilli in early life. Typhoid fever may, indeed, attack a person a second time, but such cases are rare, most of them dating back to a time when aids to accuracy of diagnosis were wanting, so that many of the supposed second attacks might be explained by the occurrence of paratyphoid or of some other continued fever. In the case of the inmates of the Independence Hospital many had doubtless been there for a number of years, and so had been protected against the sources of contagion to be met with in the outer world. To make the statistics conclusive the length of time that the typhoid fever sufferers had been in the hospital should be stated.

Manges believes that typhoid fever in the aged is often overlooked because it then runs an atypical course, and Hamilton found this to be true in the cases he studied in the Independence Hospital. The prodromal period was lengthened, and the symptoms of this stage were mild or absent. The temperature curve in the established disease conformed to the classical type, the fever being markedly remittent, or even in some instances remittent. In most cases the temperature returned to the normal from the eighth to the eleventh day, though it did not always stay there. Chills and sweats seemed to be more frequent than in young persons, and disturbances of the circulation were, as might be supposed, very common. Respiratory complications were also, naturally, more in evidence, and so were disturbances of the genitourinary system. The mental condition of the patients was not, as a rule, seriously aggravated, and in some there was a distinct improvement in the psychic condition following the onset of the fever. Convalescence was tedious, being prolonged by persistent slight elevations of temperature occurring after the curve had reached the normal, and by pulmonary complications. The death rate, as might be expected, was high, though this might be attributed less to the age than to the depressed mental and physical state of the patients when attacked. Of the 27 patients 50 years of age or over, 6 died, giving a mortality of 22.22 per cent. It would undoubtedly be less in normal individuals of the same ages.

Hamilton's study of this epidemic is exceedingly interesting as a contribution to our knowledge of the course of typhoid fever in late middle life and old age, but we think, for the reason above given, that it is inconclusive as to the liability of those of advancing age to this disease. The statistics of fever hospitals and of Boards of Health regarding the age incidence of typhoid fever are all on the side of those who regard the disease as one of youth and early adult life, and while it is evident that the disease may occasionally attack those more advanced in years, we see no reason to revise the generally received opinion that age is a protection against this and other of the common acute infectious diseases.

PULMONARY TUBERCULOSIS IN IRELAND.

Consumption is reported to be so rife in Ireland that both there and in England public attention is being acutely directed to the matter. Exhibitions dealing with the disease, organized by the most prominent people of Ireland, have been and are taking place in the principal towns. At the exhibition which was held in Dublin some few weeks ago, various well known authorities on tuberculosis discussed the situation and suggested remedies for the existing deplorable state of affairs. Even the political parties are evincing interest in the subject, and one of the most conspicuous of these bodies has, by the mouth of its president, himself a medical man, declared its intention of inaugurating a crusade against tuberculosis. Again, in a lecture given in Belfast about two months ago, in connection with the exhibition, a Dr. David Lawson drew a graphic but melancholy picture of the spread and range of the disease. It is not as if the malady were extending slowly, its sweep is remarkably rapid, and unless steps are quickly taken to check its dissemination, affairs must go from bad to worse.

When the fact is borne in mind that every year large numbers of Irish immigrants land on these shores to make their home in this country, it will be understood that the matter must be of more than academic interest to us here. Indeed, the increase and spread of tuberculosis in Ireland is a question of grave and more or less imminent moment to Americans generally, and especially to those who live in the big manufacturing cities, to which the Irish now chiefly resort. It cannot but be recognized that Irish domestic servants alone must be in some instances a source of danger, for although all those who are suffering from the disease in a stage which can be readily diagnosed will be rejected at the port of entry, it must not be forgotten that the seeds of the disease may be present in many, and will flare up under favoring conditions. Dr. Lawson drew attention to this aspect of the question and mentioned the investigations conducted at the Phipps Institute in Philadelphia, where during the past three years nearly 4,000 cases of tuberculous disease had been treated. Careful records of the parentage of the patients have been kept, and it has been ascertained that in the case of one of the parents coming from Ireland the incidence of tuberculous disease was very considerably higher than when an Irish element was absent from the union. It is also said that similar results have been obtained from investigations made in New York.

It is somewhat curious to note how tuberculosis has increased in Ireland in a comparatively short space of time. In 1870, Scotland, with a death rate of 4.9, occupied the head place on the list as regards this disease; England came next with 3.3; whilst Ireland with a death rate of 2.4 was in the happy position of being in the lowest place. In twenty-five years the relative positions have altered wholly: Scotland has fallen to 2.1, England to 1.7, and Ireland's death rate has gone up to 2.9—not a very great increase, yet a real increase nevertheless.

The causes for this change for the worse, or, we may perhaps better say, absence of improvement, in Ireland are many. Bad housing is one cause, and unsanitary conditions in the rural districts is another cause, while, of course, the wholesale emigration of the flower of the race which has been going on for so many years cannot but have had an adverse influence on public health generally, including tuberculosis. Also, no regular crusade has ever been waged in Ireland against the disease. Both England and Scotland have taken the matter seriously in hand and neither brains nor money have been spared in the endeavor to cope with the situation. The results have been splendid. Ireland has been neglected, but there is no doubt that if similar efforts are put forth in that island as have been introduced in the neighboring countries, the decrease of consumption will be, at no distant period, as patent.

The Treatment of Pulmonary Disease by Means of Artificial Pneumothorax.

The idea of putting a diseased lung at rest by causing it to collapse as the result of the injection of a gas into the pleural cavity and therefore facilitating the processes of repair has found a number of advocates since Forlanini in Italy and Murphy in this country called attention to its possibilities, though the value of the method does not yet seem to be definitely established. This is possibly due to the fact that originally the contraindications to the procedure were not clearly understood and in some instances it was resorted to when there was little real prospect of its proving beneficial. The improvement usually requires a considerable length of time for its appearance so that in pulmonary tuberculosis, for example, disease of the second lung if at all advanced, or other complications such as intestinal involvement, serve to contraindicate this form of treatment. It has also been found preferable to repeat the injections frequently, admitting only a small quantity, less than 500 c.c., at a time rather than to attempt to cause more complete collapse at the first sitting. The presence of adhesions makes it more difficult to enter the pleural cavity and gives rise to pain, as they are gradually separated by the retraction of the lung, but according to Schmidt (*Münchener medizinische Wochenschrift*, December 3, 1907) it does not form a contraindication. This observer reports thirteen cases of pulmonary disease in which he injected sterile air, but it must be admitted that his results do not seem particularly encouraging and in only two instances was the improvement really noteworthy. At best, his results like those of most workers in this field, suffer from the fact that sufficient time has not elapsed to prove anything in regard to the permanence of the apparent cures effected, and his own conclusion is that in pulmonary tuberculosis the number of cases suitable for this form of treatment is very small, that the patients must be very carefully selected, and the treatment be continued for a very long time. In eight cases of bronchiectasis the results were quite unsatisfactory, but in three instances of aspiration bronchitis or pneumonia he attributes the recovery of the patients directly to the compression treatment. In general it may be said that the method has not altogether justified the hopes of its originators, though it is not impossible that a more careful selection of cases and greater experience in technique will cause an improvement in the statistics.

A New Method of Studying Spermatozoa.

The above title is hardly a correct one, for although the manner in which the method in question is applied is new, the principle involved is one that was used with great satisfaction by the microscopists of a generation ago. Before the days of the Abbé condenser and oil immersion objectives, and before the modern technique of embedding and staining tissues had been perfected, it was customary to resort to various devices for increasing the scope of the inadequate instruments that were the best then available. Since then these ingenious parabolic mirrors and prismatic reflectors have been found useless or unnecessary and the dark ground illumination that was so effective in displaying the beauties of diatoms or radiolarians is but seldom resorted to in zoological or medical work. The study of that fascinating but difficult object, the *Spirochæta pallida,* has caused investigators to resort to every possible aid that could be invoked, and a new form of dark ground illumination, representing a modification of the ultra microscope of Siedentopf and requiring a special form of substage and the use of the electric arc as the source of illumination, has been found very satisfactory for the purpose. Objects too small or too transparent to be visible by transmitted light are seen by the reflected rays as bright bodies against a black background and certain details not ordinarily evident are brought to view. The spirochetes and allied organisms have been thoroughly studied by this method, but we believe Posner (*Berliner klinische Wochenschrift,* December 16, 1907) has been the first to point out the advantage of using it in connection with the seminal fluid. Under these conditions the spermatozoa appear as silvery structures in motion on a dark field, and certain details seen with difficulty or not at all in fixed and stained preparations become plainly visible. Among these is the existence of a collar of protoplasmic granules surrounding the so-called middle piece and extending in a thinner layer over the tail also. This has already been described by several authors who regarded it as an occasional abnormality of the spermatozoan bearing it, but Posner considers that it is a normal structure. He found that it did not exist in the spermatozoa obtained by testicular puncture from a patient suffering from azoospermia. He accordingly suggests that by means of the dark ground illumination method evidence may be obtained in regard to the fertilizing power of the spermatozoa, information that under some circumstances might be of considerable importance.

Featural Surgery.

Men and women are continually twitching their features under the play of the slightest emotions, and the muscles so contracted may in time become permanently shortened, giving a fixed expression to the face. Thus we have a group of muscles which advance the lower lip in the median line, and are frequently brought into action, particularly when there is a feeling of more or less despondency. This advance of the lower lip is accompanied by a slight contraction of the orbicularis oris and the muscles of the angle, so that the corners of the mouth turn downward, giving the appearance of sadness. This display of emotion becoming a habit, the features are drawn out of shape by the overuse of the muscles, so that finally the angles of the mouth are deflected, whether the person be sad or glad. Miller, writing in the *American Journal of Clinical Medicine* for October, 1907, considers this to be one of the most frequent featural imperfections, and as a cure practises subcutaneous section of the muscles used to excess. The orbicularis oris, the muscles which elevate the lower lip, and those of the angle are sectioned subcutaneously through punctures made within the mouth. A cataract knife is entered within the angle of the mouth and is carried outward until it is beyond the bundle of muscular fibers, which may be felt with the fingers; the muscles of the chin are severed by passing the knife through the lip, traversing a fan-shaped area. By section, the action of the muscles is not overcome entirely, for they are too intimately connected with the skin; it is merely diminished, not destroyed. Miller found the operation to be of decided value in overcoming the faulty overaction of the muscles, and claims it to be of undoubted cosmetic value.

Radiotherapy in Renal Tuberculosis.

Experience has shown that tuberculosis of the kidney must be regarded as a surgical disease. None the less, although nonoperative measures offer so little in the way of encouragement they must be resorted to, either because the renal condition is only one phase of general tuberculosis, because it has become too far advanced, or because the patient will not consent to surgery. When this is the case the prognosis is very bad. Strümpel, for example, saying that the patients usually die within a few months or at most live but a year or two. Any procedure, therefore, that holds out any brighter prospects deserves consideration, and according to Bircher (*Münchener medizinische Wochenschrift,* December 17, 1907), the use of Röntgen ray fulfills this condition. He reports two cases, both of the patients being young women, in which operation could not be performed, in the one instance because both kidneys were involved and there was advanced tuberculous cystitis, and in the other in which one kidney was healthy because the patient refused her consent. In both cases the daily application of the Röntgen rays to the lumbar region during a period of a number of weeks apparently effected an arrest, if not a cure, of the disease. In one case the improvement had lasted three years without relapse; in the other there was a slight recurrence of symptoms at the expiration of two years which promptly subsided under a renewed application of the rays. Such results seem too much at variance with the ordinary course of the disease to be ascribable merely to the beneficial effects of the rest in bed, tonics, proper hygiene and diet, etc., that hospital treatment involves.

Blood Pressure as a Prognostic Sign in Eclampsia.

In cases of eclampsia in which either cerebral hemorrhage, pulmonary embolism, or edema of the lungs sets in after a single convulsion, a prognosis is easily given, as it is usually fatal. When these conditions do not occur, long-continued coma or its presence before a convulsion, a continued high temperature and leucocyte count, convulsions in rapid succession, a small, soft, rapid pulse, a markedly diminished amount of urea and urine, all warrant a bad prognosis; while, if conditions are reversed, the peril becomes more remote. In spite of these facts, the prognosis in each individual case is often uncertain. A more certain prognostic sign has recently been reported by Vaquez in the *Semaine médicale,* No. 11, 1907. He found that the blood

pressure in an eclamptic patient rose even before a convulsion, reaching its highest point just before the attack; when it remained high after the attack the case almost always terminated fatally, but if it came down to normal soon after, the prognosis was good, even though the blood pressure rose again before a subsequent convulsion. According to Vaquez the blood pressure of a pregnant woman varies between thirteen and fifteen centimeters (sphygmomanometer of Basch-Potain), increases slightly during labor, and comes down to normal soon after delivery. In eclamptics it rises to twenty or twenty-five centimeters, a condition which is confirmed by feeling the pulse and hearing an accentuated second aortic heart sound. If the sphygmomanometric reading is nineteen or twenty soon after the convulsion the prognosis is bad, while if it is ten or twelve it is good.

The Treatment of Anthrax.

In regard to the treatment of few surgical infections does so much disparity of opinion exist as is the case with anthrax. Many authorities, perhaps the majority, are in favor of more or less radical procedures whenever the lesion is in an accessible situation, and widespread excision of the pustule, extensive cauterization with the hot iron or chemical agents, and the application or injection of powerful antiseptics, are all warmly recommended. Others use no local treatment whatever, or advise merely local applications with suspension of the part and perfect quiet. That the average mortality of the infection is very high is shown by Sclavo's statistics collected in Italy, which gave 24 per cent. of deaths in over 24,000 cases treated in many different ways. Barlach has recently (*Münchener medizinische Wochenschrift*, 1907, No. 15) reported ten cases without a death in which very energetic cauterization with the thermocautery and incision together with the injection of tincture of iodine and local applications of bichloride were resorted to, while Creite (*Deutsche medizinische Wochenschrift*, 1907, No. 51) reports another series of thirteen cases in which the treatment consisted of absolute quiet with suspension of the affected member and wet dressings of aluminum acetate, also without a death. The latter author, from his review of the literature, reaches the conclusion that the more conservative treatment is just as effective as the other, while it does not involve the risk of disseminating the infection through the blood stream that attends incision or other active manipulation of the pustules. It might be added that Sclavo's serum has also been found efficient, for this observer reports 164 cases treated with serum with the mortality of 6 per cent.

News of the Week.

Fifth Pan-American Congress.—The next Pan-American Medical Congress is to be held in Guatemala City, on August 5 to 10, 1908. At this season of the year there is said to be but little rain and the heat is not excessive, as Guatemala City is situated on a plateau. The trip to the Congress and back will be managed by the Committee on Transportation, and excursion trips may also be made, in connection with the Congress, to Mexico or the various West Indian Islands. There will be no charges for transportation in the Republic of Guatemala. The Congress will be held under the presidency of Dr. Juan J. Orteaga, with Dr. José Azurdia as secretary. The secretary of the International Executive Committee is Dr. Ramon Guiteras, 75 West Fifty-fifth street, New York.

Harvey Society Lectures.—The fourth lecture in the Harvey Society course will be delivered at the New York Academy of Medicine on Saturday evening, January 11, 1908, at 8:30 P. M., by Prof. Ernest H. Starling of the University of London. Subject: "The Chemical Control of the Body." All interested are cordially invited to be present.

London Suicide Bureau.—The report of the Salvation Army antisuicide bureau started in London a year ago shows that 1,125 men and 95 women applied to the bureau during the past twelve months. Most of these belonged to the middle classes, and more than 50 per cent. of the men attributed their distress to financial embarrassment or poverty, 11 per cent. to drink, drugs, and disease, and 21 per cent. to accidents, sickness, and other misfortunes. Two-thirds of the women were suffering from melancholia caused by poverty and the remainder from drugs and drink. The bureau was founded for the purpose of giving advice and encouragement, but no direct financial aid. Its managers estimate that about three-quarters of those who applied were diverted from their purpose.

Hospital Ship under Medical Command.—Acting under orders of the President, Secretary Metcalf has assigned Surgeon Charles F. Stokes to the command of the hospital ship *Relief*, which is being fitted out at the Mare Island (Cal.) Navy Yard with a full equipment for special duty with the battleship fleet. The *Relief* is to be placed in commission as soon as possible with a sailing master and crew from the merchant service.

Drug Clerks Scarce.—Although the salaries of drug clerks have risen almost fifty per cent. within the last few years, there is said to be a scarcity of applicants for clerkships owing to the more rigid requirements of recent legislation in regard to the licensing of pharmacists.

International Conference on Sleeping Sickness.—The Second International Conference on Sleeping Sickness, which was to have been held in November, will probably not convene until February in London. The delay is due to the request of the German government, which wishes to present the results of Koch's expedition in East Africa.

Dermatological Institute Fined.—The owners of a widely exploited "Dermatological Institute," which advertised its ability to make crooked noses straight, eradicate wrinkles, etc., were last week found guilty in the Court of Special Sessions of misdemeanor in practising medicine without registration and were fined $100 each.

Smallpox at Kingston, N. Y.—About eighty cases of smallpox, most of them mild, have occurred in Kingston, the infection apparently having been brought in by returning hop pickers from other parts of the State. All places of amusement, the public halls, and the schools have been ordered closed for two weeks, and one of the school houses has been converted into an emergency hospital. The mildness of the first cases rendered the diagnosis difficult and fresh cases occurred before the true nature of the disease was recognized.

Public Cigar Cutters a Source of Danger.—The German health officials are considering abolishing the devices for cutting off the ends of cigars that form a familiar part of the equipment of tobacco shops. It is alleged that many smokers make use of the instrument after having already placed the cigar in their mouths and therefore render possible the transfer of disease germs to other smokers.

Against Cigarettes in Michigan.—In the constitutional convention at Lansing a proposal prohibiting the manufacture and sale of cigarettes in Michigan was adopted, but has yet to pass a second reading.

"Outlook for the Blind."—The third number of the first volume of this admirable publication, which is devoted to promoting the welfare of the blind, contains among other valuable contributions an article by Dr. F. Park Lewis on "The Prevention of Unnecessary Blindness." The journal is edited by Charles F. F. Campbell, 277 Harvard street, Cambridge, Mass.

Typhoid Investigation in Trenton.—Under the direction of the Joint Health and Water Board Committee of Trenton, N. J., an attempt is being made to ascertain the origin of the recent typhoid epidemic in that city, by a house-to-house canvass by sanitary inspectors, who are investigating the source of milk supply, the consumption of raw osyters, etc.

Codification of Regulations of the Chicago Health Department.—The council committee on health has begun to legalize the rules of the city health department. It recommends for passage two ordinances, one codifying the present rules of the department for the care and prevention of contagious diseases, and the other providing for the handling of night soil.

Study of Speech Defects.—A special chair on stammering and other speech defects has been established at the University of Berlin. Professor Gutzmann, who has been appointed the first incumbent of the chair, says that at least one per cent. of German school children between the ages of six and fourteen stutter and that many more have other defects in speaking. Over 1,000 recruits are rejected annually by the military authorities on account of speech defects of one sort or another.

Vaccination Rule Sustained in Chicago.—The vaccination rule of the Board or Education of Chicago was recently upheld in the Circuit Court in the mandamus suit instituted by a citizen to compel the Board to admit his daughter, seven years old, to the John Fiske School, although she had not been vaccinated.

Confederation of Students' Societies.—The students of the University of Pennsylvania Medical School have formed an organization the purpose of which is to acquaint the undergraduates with the workings of the American Medical Association. The various student societies elect members to a House of Delegates which transacts all the business of the association. An annual meeting will be held at which papers will be read. The organization is named "The Undergraduate Medical Association of the University of Pennsylvania" and already has over two hundred and fifty members.

Annual Report of Warden Happel of Cook County Hospital.—During the year 1907 there were 28,932 patients in the hospital, as compared with 27,957 in 1906. The average daily number was 1,145, the year before 999. The deaths in the county hospital numbered 2,370, in 1906 2,027. During 1907 the hospital treated 126 cases of deformities, 187 cases of appendicitis, 165 persons suffering from gunshot wounds, and 5,574 cases of infectious diseases. Mr. Happel expresses satisfaction with the work accomplished.

New Isolation Hospital in Chicago.—Bids for the erection of the new isolation hospital in Chicago were recently opened by the Department of Public Works. The total of the low bids was $41,263. The new hospital, which is designed for twenty-five beds, will accommodate the smallpox cases, leaving the present isolation hospital as a place of treatment for other contagious diseases, an institution which the city long has needed.

To Improve Service at Chicago Hospitals.—Agitation for the better administration of institutions for the healing of the sick and injured is the main purpose of a new organization which was recently formed and which will be known as the Chicago Hospital Association. The officers are: *President*, Asa Bacon; *Vice-President*, Charles T. Garrard, Illinois Charitable Eye and Ear Infirmary; *Secretary*, Anna L. Davis, Francis Willard Hospital; *Treasurer*, Dr. L. Ryan, St. Anthony's Hospital.

Sydenham Hospital.—The following adjuncts of the Sydenham Hospital have resigned: Drs. Richard Weil, Richard Lewisohn, Arthur Stein, Joseph E. Fuld, Dewitt Stetten, A. Richard Stern, and Ernst Danziger.

College of Physicians of Philadelphia.—At the annual meeting held January 1 the following officers were elected for the ensuing year: *President*, Dr. James Tyson; *Vice-President*, Dr. G. E. de Schweinitz; *Secretary*, Dr. Thomas R. Neilson; *Treasurer*, Dr. Richard H. Harte; *Honorary Librarian*, Dr. Frederick P. Henry.

St. Louis Medical Society.—At the meeting of this society held on December 28 the election of officers resulted as follows: *President*, Dr. Herman Tuholske; *Secretary*, Dr. C. E. Burford.

Coos County (N. H.) Medical Society.—This society elected the following officers at its meeting held in Whitefield on December 26: *President*, Dr. C. E. Hight of Groveton; *Vice-President*, Dr. E. R. B. McGee of Berlin; *Secretary-Treasurer*, Dr. F. W. Evans of Coos.

Marion County (W. Va.) Medical Association.—The following were elected officers at the annual meeting of this organization held in Fairmont on December 26: *President*, Dr. F. W. Hill; *Vice-President*, Dr. C. W. Waddell; *Secretary*, Dr. J. W. McDonald; *Treasurer*, Dr. W. H. Sands.

Jefferson County (Ala.) Medical Society.—The election of officers for this society held at the meeting in Birmingham on December 23 resulted as follows: *President*, Dr. L. W. Whatley; *Vice-President*, Dr. W. F. Black; *Secretary-Treasurer*, Dr. Arthur Toole, reelected.

Bates County (Mo.) Medical Society.—At the meeting held in Butler on December 19 officers as follows were elected: *President*, Dr. T. F. Lockwood of Butler; *Vice-Presidents*, Dr. Maud R. Agniel of Rich Hill and Dr. Rhodes Foster; *Secretary and Treasurer*, Dr. E. N. Chastain of Butler.

Howard County (Neb.) Medical Association.—The following officers were elected at the meeting of this association held in St. Paul on December 19: *President*, Dr. E. R. Fletcher of St. Paul; *Secretary and Treasurer*, Dr. P. M. Peterson of Danneborg.

Honor for Mr. Nathan Straus.—Mr. Nathan Straus, who has recently presented to several European cities milk pasteurizing plants, has been spending some time in Heidelberg demonstrating to visiting officials the workings of the outfit given by him to that city, and has had an audience with the Dowager Grand Duchess Louise, who expressed

her appreciation of his efforts to reduce infant mortality.

Dr. E. Franklin Royer has resigned as chief resident physician to the Municipal Hospital of Philadelphia.

Death of Professor Hoffa.—A cablegram received by Dr. Reginald Sayre of this city announced the death on Monday of this week of Dr. Albert Hoffa, the well-known orthopedic surgeon and professor at the University of Berlin. Professor Hoffa visited this country in 1904, when he was a guest of the American Orthopedic Association. At that time the Jefferson Medical College conferred upon him the honorary degree of doctor of medicine.

Obituary Notes.— Dr. Daniel S. Hardenberg of Jersey City died on January 1 in his sixty-eighth year. He was graduated from the Albany Medical College and served through the Civil War as assistant surgeon in the Fifty-ninth New York Volunteers. He had been a resident of Jersey City for forty years, but was compelled to give up active practice about five years ago owing to failing health.

Dr. F. Gordon Morrill of Boston died at Assouan, Egypt, on December 28 at the age of sixty-four years. Dr. Morrill was a native of Boston and was graduated from Harvard in the class of 1869. He was the son of the late Dr. Samuel Morrill and the father of Dr. Gordon N. Morrill of Boston. About six weeks ago he left Boston to spend the winter in Egypt, and his death occurred shortly after reaching Assouan.

Dr. George Dunsmore of St. Albans, Vt., died on December 29 of pneumonia at the age of seventy-nine years. He was born in Coteau, Que., and was graduated from Castleton Medical College in 1855, afterwards entering the University of Cincinnati, from which he was graduated in 1871. He had practised for many years in Burlington and St. Albans, and had been president of the Vermont Medical Society and the Franklin County Medical Society.

Dr. Daniel E. Bartlett of Seattle, Wash., died suddenly on December 19 at the age of twenty-nine years. He was a native of Cambridge, Mass., and was graduated from Harvard Medical School in 1904. He had been practising in Seattle for about a year.

Dr. Jesus Onate of Mexico City died on December 20 at the age of eighty-nine years. Dr. Oñate was the oldest practitioner in Mexico, having been engaged in active work for sixty-two years.

Dr. John D. Scott of Roanoke, Va., died suddenly on December 28 at the age of seventy-nine years. He had practised in Southwestern Virginia for fifty-nine years.

Dr. Parks L. Kabler of Hannibal, Mo., died on December 26 after a lingering illness. Dr. Kabler was born in St. Charles County, Mo., in 1853 and was graduated from the Missouri Medical College in 1879. He practised for the next eight years in Warren and Lincoln Counties and then removed to Hannibal. For many years he was chief surgeon for the Burlington Railroad and for a time was secretary of the Board of U. S. Pension Examiners.

Dr. Alva A. Hoag of Bridgeport died of pneumonia on December 30 at the age of forty-seven years. Dr. Hoag was born in Danesville, Vt., and was a graduate of the New York Homeopathic Medical College. He had practised in Bridgeport for twenty years.

Dr. John Y. Hoffman of Reading, Pa., was killed on December 26. He was forty-nine years old and was graduated from Jefferson Medical College in the class of 1880. He was at one time Prison Physician, later Coroner, and afterward City Treasurer of Reading.

Dr. Peter F. Shaw died at Mt. Bethel, Pa., on December 25. He was graduated from the Eclectic Medical College of Philadelphia in the class of 1886.

Obituary.

NICHOLAS SENN, M.D.

CHICAGO.

Dr. Nicholas Senn of Chicago died January 2, 1908, of heart disease and acute nephritis after an illness of ten weeks contracted in the high altitudes of South American mountains during his recent trip to that continent. He was born in the canton of St. Gall, Switzerland, October 31, 1844, and came to the United States with his parents in 1853, when the family settled at Ashford, Fond du Lac County, Wis. He was graduated from the Chicago Medical College in 1868 and then went to Munich for post-graduate study. Upon his return to Chicago he was appointed house physician of the Cook County Hospital. In 1869 he returned to Fond du Lac and entered practice there, remaining until 1874, when he went to Milwaukee. In 1884 he was made professor of surgery of the College of Physicians and Surgeons, Chicago; in 1890 professor of practical and clinical surgery, Rush Medical College. He was also professor of surgery, Chicago Polyclinic Hospital; professor-lecturer on military surgery, University of Chicago; he was American delegate to the International Medical Congress, Berlin, 1890, and Moscow, 1897, and delegate for the United States to the International Red Cross conference, St. Petersburg, 1901. During the Spanish war he was chief surgeon of the Sixth Army Corps, and at the close of the war was brevetted Brigadier General. Dr. Senn was an unusually voluminous writer and made many important contributions to medical literature.

ROBERT WILLIAM TAYLOR, M.D.,

NEW YORK.

Dr. Robert W. Taylor of this city died suddenly on January 5, of disease of the heart complicating nephritis, from which he had suffered for several years. He was born in London, August 11, 1842, but came to this country in early life. He studied medicine here, and was graduated from the College of Physicians and Surgeons with the class of 1868. He early turned his attention to dermatology and venereal diseases, and achieved an enviable reputation in that field. He was formerly professor of diseases of the skin at the Woman's Medical College, New York, and at the University of Vermont, Burlington. He was also consulting genito-urinary surgeon to the City (Charity) and Bellevue Hospitals, and consulting surgeon to the French Hospital. He was the author of "A Practical Treatise on Sexual Diseases of the Male and Female," the third edition of which appeared in 1905. He was a member of the Medical Society of the County of New York, of the American Medical Association, the New York Dermatological Society, the American Dermatological Association, the American Association of Genito-Urinary Surgeons, and the New York Academy of Medicine.

Correspondence.

CHLOROFORM ANESTHESIA.

To the Editor of the Medical Record:

Sir:—I was much interested by Dr. J. D. Bryant's article on "Some Unclassified Dangers in Anesthesia" and the discussion of the same in your issue of December 28.

It is possible that what I may write on the use of chloroform as an anesthetic may be of but little value, but as I have, during my entire professional life, in which I have, perhaps, done a full share of surgery in a village of this size, and commanding patients from the surrounding territory, used chloroform only, and never with any dangerous effects, it is but natural that so far as my experience teaches chloroform should be thought by me to be the best anesthetic. The safety of any anesthetic depends upon the care and attention given during its administration. The administration of all anesthetics is accompanied with danger, and this must be reduced to the minimum by proper administration. I wish some one would collect statistics of the number of deaths from "ether pneumonia," as I believe that if these cases were charged to the death rate of ether it would be equal to that from chloroform. In the administration of all anesthetics in our large hospitals there is too much attention paid to complicated apparatus for giving it, and not enough to the patient. I use always an Esmarch's inhaler, with two thicknesses of gauze over it. If one will place such an inhaler well down over the nose and mouth there will be a perfect, free, and pleasant respiration. The supply of air is ample. That is the first point in anesthetic safety. Now with the inhaler in place, begin your anesthetic by dropping on the inhaler where its ribs cross in the center, and not in any other place. This is the second point in administration, for by thus dropping in one place the evaporation of the chloroform is regular because from the same point of supply.

Now the next point is the regulation of the dosage of chloroform, and this you get by the rapidity or slowness with which you drop. Begin by dropping very slowly, and gradually increase the rapidity of dropping, as the confidence of the patient is gained, watching closely all the time the pulse and respiration until the patient comes under its influence, often without a struggle. Of course when the desired state of anesthesia is obtained then the dosage is less or more, as indications require, and you do not overwhelm the patient by an overdose of chloroform or underdose of air. By this method the dosage can be measured almost as accurately as that of medicine given by the mouth, because you know the number of drops given and that there is enough air obtained and a uniform evaporation of chloroform from a given point.

If for any reason it is desired to interrupt the anesthesia, remove the inhaler entirely and replace it again as before, with the inhaler well down on the nose and mouth in a fixed position, and begin anew as above described. Given in this way one will be surprised at the small amount of chloroform used and the quiet with which the patient will pass under its influence. If the patient is nervous I often let him breathe for a few minutes with the inhaler in place before dropping any chloroform at all, and then very slowly at first to gradually accustom him to it and to allay fear.

I never put vaselin on the face as a protective and never have burning of the skin. The dropper is an ordinary ground glass, grooved stoppered drop bottle of the drug stores.

I am fully aware that the majority of the profession in this country does not use chloroform in surgery, but I think if administered carefully it will come into more general use in America, as it is in Europe, where during a year's stay I saw ether used only twice, once at St. Thomas' Hospital, London, and once at Leopold's in Dresden by an American interne.

T. M. McIntosh, M.D.

Thomasville, Ga.

OUR LONDON LETTER.

(From Our Special Correspondent.

THE HOSPITAL FUNDS: KING EDWARD'S, THE SUNDAY—BRADSHAW LECTURE AT R. C. S.: TUBERCULOSIS OF GENITO-URINARY APPARATUS—PNEUMOCOCCUS INFECTIONS—DR. H. JACKSON—OBITUARY.

London, December 20, 1907.

On Monday there was a meeting of King Edward's Hospital Fund for the purpose of awarding grants for the present year. The Prince of Wales, as president, took the chair and in an interesting speech gave a summary of the year's work and touched on some of the chief recommendations. It is the duty of the president to nominate the members of the committees to which so large a part of the work is delegated, and his Royal Highness decided to proceed on the principle of appointing each member to only one committee, but thought the honorary secretaries should have the right to attend all committees but to vote only on the one to which they belong. Under the Act of Parliament which gives the constitution on broad lines, the president pointed out that the council is to be reconstructed every year and therefore "what is decided to be best now is not an immutable law for future generations, or even for the year after next." The resolutions that had been prepared and were duly passed will no doubt be formally confirmed in January next. The Prince reported that the sum recommended for distribution this year reached £120,000 and on two or three items in the grants offered a word of explanation. A very exceptional sum of £15,000 had been allocated to Guy's Hospital and he hoped this would not be misunderstood, for the rebuilding of the out-patients' department had been delayed to the detriment of the poor. The King's Fund would certainly in the end contribute £10,000 and it was proposed to pay it all at once instead of spreading it over several years. The work would be completed the sooner and the men employed on the building would be benefited by the work provided for the winter months. A grant of £6,000 to King's College removal fund brings up the amount devoted to that object to £22,000. The amalgamation of the Orthopedic Hospital had been completed. The negotiations between the Throat and Ear Hospitals were continuing. The fund had made a liberal offer to the Hampstead Hospital to amalgamate with the Northwest London. One other subject of the speech is important, viz., the late period at which certain hospitals issue their annual reports and accounts. The committee proposed that they should not be later than April 15 in future, so that the statistics of the Fund need not be delayed, and the president thought it not unreasonable to expect three and a half months to be sufficient for any hospital to prepare its report.

On Tuesday the annual meeting of the Sunday Fund followed, when the Lord Mayor occupied the chair. The report drew attention to the large number of country patients treated in the metropolitan hospitals—estimated at 25 per cent.—and announced that an appeal would be made this year for contributions toward their cost. The distribution committee recommended awards to 159 hospitals, 57 dispensaries and 27 nursing institutions, the total sum thus divided amounting to £68,134. The adoption of the report having been moved and seconded, the Rev. L. S. Lewis as a representative of the Church Antivivisection Society wanted to know why the Battersea Hospital received no grant, and the Lord Mayor having said for reasons which seemed good to the committee, Mr. Lewis declared it was only because remedies produced by vivisection were not permitted, and he moved that before adopting the report the question be referred back to the distribution committee. A little scene followed on the president requesting him to confine himself to facts, and the amendment found a seconder. The Lord Mayor read a resolution of the committee expressing the opinion that the Antivivisection Hospital did not comply with those general conditions which should govern any hospital designed to give the best form of relief to the sick poor and therefore could not be recommended for a grant. Mr. Sydney Holland protested against the introduction of ill-feeling by one who should be a harbinger of peace and said the hospital was a miserable one, miserably built and miserably equipped, and its work was not based on considerations for the benefit of the patients. The amendment was eventually put and twelve hands were held up for it, after which the original resolution was of course carried by an overwhelming majority.

The Bradshaw lecture at the College of Surgeons was delivered by Mr. Rickman Godlee and naturally afforded some contrast to that at the College of Physicians, of which I have previously given you some account (Medical Record, December 5). Mr. Godlee's subject was "Prognosis in Relation to Treatment of Tuberculosis of the Genitourinary Organs" and he treated it with great perspicacity, as it has presented itself to him in the course of his extensive experience. At the conclusion he said if anyone murmured that he had only given the views of a single observer, and a statement directly opposed might be obtained across the street, he could only reply that it would have been a simpler but not easier task to collect views of all kinds bearing on the subject. Anyone seeking such he referred to Cornet's gigantic work, "Die Tuberculose," in which is a bibliography of fifteen pages devoted to the urogenital apparatus. As to the value of such knowledge,

he remarked that it is no satisfaction to a patient to know, *e.g.* the mortality of nephrectomy or the percentage of those who have shown signs of tuberculosis in the opposite kidney after the operation. He rather wants to know his own particular chance whether he keeps or parts with his kidney. But such knowledge is not to be got through statistics. Each case must be judged on its own merits and it is only experience that can justify an approximate answer. The lecture closed with the remark that if he should be the means of preventing one unnecessary nephrectomy or of preserving to one poor wretch the internal secretion of his testicles the Bradshaw bequest and his own efforts would not have been spent in vain. This remark will indicate to you pretty plainly that Mr. Godlee holds rather a conservative view of the subject, and indeed the whole lecture may be regarded as a protest against the operative furor that has seemed to possess some surgeons. It seems at times to be forgotten that the human body offers a distinct resistance to the attacks of the tubercle bacillus. The resistance may be less strong than in the case of many injurious influences, but is not to be altogether disregarded. In certain forms of tuberculosis the modern tendency is to regard it as curable, though in the case of a single focus the usual teaching is to extirpate it, provided that no evidence of a deposit elsewhere can be obtained by the most exhaustive examination. In the case of twin organs the question arises whether there is a chance of the fellow escaping even although it appears unaffected, and further what is the probable effect on the system if one twin be left and afterwards is attacked. These and other points were discussed by Mr. Godlee with an acumen and fullness of experience worthy of his position. It may interest your readers if I add a few words about these Bradshaw lectures. They were endowed by the widow of Dr. W. W. Bradshaw, D.C.L., who practised some time at Reading and Andover. Mrs. Bradshaw left a sum of money in consols to provide an annual lecture at the Royal College of Surgeons and another at the Royal College of Physicians. Mr. Godlee in some prefatory observations remarked somewhat cynically that while consols and the two colleges exist the name of Dr. Bradshaw will be revived every year in London, and such a foundation seemed the simplest method of securing a limited immortality. He added that he could imagine the doctor, looking down from an exalted state of purity and wisdom and watching those who undertook the lecture rack their brains for ideas. To this one might well retort that at any rate Mr. Godlee himself has not racked his brains in vain.

The Medical Society of London has had a discussion on pneumococcus infections. It was introduced by Professor Osler, who said the death rate from these infections had steadily increased for the last ten years in this country, but not at so great a ratio as in American cities. He thought we were face to face with a most serious situation in preventive medicine, which deserved organized study as much as tuberculosis or cancer. Inflammation of the lungs was the chief but not the only disease due to pneumococcus, of which there were varieties in morphological characters and virulence. Many people carried about a potential infection of the upper air passages. In some cases meningitis had spread from the accessory sinuses. Pleurisy and empyema occurred from direct infection from the lungs. Cardiac cases might arise from the lung or independently. Peritonitis was the most fatal of abdominal infections. Meningitis was the third in order of frequency among cerebrospinal inflammations. Pneumococci were present in the mouth and throat of a considerable proportion of healthy persons and atypical strains were more common in such persons than in pneumococcic patients. The latter expelled the pneumococci in coughing and talking, as also do those with catarrh. From such they might be acquired by those attending them. A complete disinfection of the mouth was almost if not quite impossible, but the professor recommended a wash containing alcohol, sodium bicarbonate, sodium chloride, and glycerine. He discussed the question of having separate wards for pneumonia. To this it was objected by a subsequent speaker that there was no evidence of cases arising *de novo* in hospitals where there was free ventilation and the sputa were sterilized. Professor Osler also described cases of pneumococcic infection without any local lesion, and the president, Dr. Kingston Fowler, also described such a case, his impression being that it was an infection of a lower grade. Another speaker traced acute inflammation of the mediastinum to the same cause. Dr. West remarked that complications were rare in pneumonia and perhaps there was a tendency to group together affections which were not associated with the organism as closely as at present was supposed.

Dr. Rolleston said pneumococcic peritonitis was rare, but attracted attention because it was primary. It was most often met with in young females, and so a suggestion had been made that the organism might enter through the Fallopian tubes. The onset was sudden, but the symptoms soon subsided and diarrhea, suggesting typhoid, succeeded or if prolonged, a condition resembling tuberculous peritonitis. Dr. Poynton spoke of the infection in children under twelve, suppurative pericarditis being the most frequent form, and the difficulty of diagnosis extreme. In 100 cases found in the post-mortem room only five had been discovered during life.

Mr. Sydney Stephenson described the part played by the organism in diseases of the eye and its appendages.

A marble bust of Dr. Hughlings Jackson has been placed in the hall of the National Hospital for the Paralyzed and Epileptic to commemorate the services of the "father of British neurology" to that institution.

Dr. Ed. L. Fenn, J.P., Consulting Physician to the Colchester Hospital, and formerly in practice for many years at Richmond, where he was also physician to the hospital, died on the 8th inst. He retired in 1903, but continued to take a great interest in medical matters and in the local institutions and societies he had served. He was a King's College alumnus and presided at the dinner in 1892, in which year he became a member of the Royal College of Physicians, his earlier qualifications dating 1865. He was in his sixty-eighth year.

Dr. George H. Graham, who had been for five or six years medical officer to the Electrical Department of the East London Children's Hospital and assistant physician to the Leaman's Hospital, has died at the early age of forty-seven, to the great regret of his colleagues and host of friends. He had studied the Light treatment under Finsen. His electrical work was based on a thorough knowledge of the science involved.

Progress of Medical Science.

Boston Medical and Surgical Journal December 26, 1907.

The Results of the Chemical Investigation of Tumors.—S. P. Beebe analyzes the work of recent years along the lines indicated in the title of his paper. So far as concerns inorganic elements, we find sulphur, phosphorus calcium, potassium, and sodium. Actively growing neoplasms contain a much larger amount of sodium and potassium and a much smaller amount of calcium than do old necrotic growths. As to proteid constituents, Petry has shown that carcinomata are relatively richer in nucleoproteid and poorer in globulin and albumin than control normal tissues from which the growths had originated. The large quantity of nucleo-proteid found in a tumor corresponds with the histological structure, and a large quantity of non-coagulable nitrogen is the logical sequence of the autolytic processes of such tissues. The distribution of nitrogen in the tumor extract varies within wide limits, depending upon the state of the tissue as regards necrosis and also depending upon the method of preparing the extract. No definite toxin has yet been isolated from tumors. Beebe has observed in the course of immunization experiments that extracts of tumors, and particularly necrotic tumors, have a much greater toxic effect upon the animal inoculated than extracts of normal organs, and a few direct experiments show that a much smaller amount of tumor nitrogen is required to produce a fatal result than is required from extracts similarly made from autolyzed normal organs. Tumors also contain hemolytic substances. As to enzymes the author states that a demonstration that a malignant tumor contains an enzyme capable of absorption in the body fluids, and capable of marked digestive effect upon other tissues under physiological conditions, would be a contribution of definite value, and is something we now lack. It may be that the toxic properties of tumor extracts are in large part a function of the hemolytic and heterolytic activity.

Strain as a Causative Factor in Infectious Arthritis.—J. D. Adams presents a series of six cases, women, all dressmakers, presenting evidences of infectious arthritis in the hands as shown by deformities, pain, tenderness, swelling, and incapacity for work. All the cases show many common factors, as vocation, seat of disease, sequence of joints attacked, symptoms, and relief treatment. All the patients worked in good surroundings and on very heavy goods. It will also be noted that the symptoms were first noted in the thimble finger, and the histories show a progressive infection of the joints in right hand before any symptoms occurred in the left. The onset was more or less insidious and symptoms not especially acute, but in all the cases intensified greatly with use [illegible] pain,

intermittent in character, was more in the nature of a soreness rather than the throbbing pain of an infection. The symptoms were not affected to any extent by sudden changes of temperature. In all the cases there was absolutely no indication of any trouble in any other joint in the body. As to treatment, details of which are given, the author found the best results to follow from the omission of all meats from the diet, forced use of liquids, sodium benzoate, gr. v. t. i. d. to neutralize acidity (as all showed a hyperacidity of the urine) and daily baking. The results were most gratifying. The counterirritation of the heat produced the usual hyperemia to a marked degree, and all the cases showed a gradual diminution of pain, with a return on failure in systematic baking. The cases pursuing the treatment conscientiously for two months had entire relief from pain, with ability to return to work.

New York Medical Journal, December 28, 1907.

The Oxychloraniline Reaction for Free Hydrochloric Acid.—This test, which is described by R. L. Pitfield, depends on the oxidation of aniline oil or aniline hydrochloride in the presence of potassium chlorate by a mineral acid or acid salts. By inverting a cold enameled spoon over a capsule containing chyme and slightly warming the capsule a few drops of moisture are collected in the spoon. To this fluid a few drops of the following are added and the whole treated to evaporation: Aniline, 10 c.c.; alcohol, 50 per cent.; 10 c.c. potassium chlorate to saturation. By this method all danger of charring is obviated. This is quite an advantage, and is a simple and convenient method. The few drops of moisture contain hydrochloric acid if it was present in a free state in the chyme. But strong heating of the chyme must be carefully avoided, since not only free but combined hydrochloric acid will be liberated and a reaction for free hydrochloric acid obtained when none was present. So gentle warming is always indicated. Hydrochloric acid seems to be as volatile, or more so, than water. The author explains in detail the chemical reactions which take place in the test which, if positive, reveals a bluish deposit on the spoon. He considers the test a more delicate one than the Günzberg test (vanillin and phloroglucin), but less delicate than the resorcin sugar test of Boas.

Silver Nitrate in Gastric Diseases.—H. Weinstein recommends the use of this remedy in all irritative conditions of the gastric mucosa characterized by increased secretion, hyperacidity of the gastric juice, nausea, vomiting, and pain. It is useless in the mere neuroses. He usually administers it in solution in doses of one-quarter to one-half a grain three times daily on an empty stomach. For half an hour after it is taken no food or drink should be swallowed. The author rarely finds it necessary to continue its employment for a longer period than three weeks, although in rebellious cases it may be kept up for a month without danger of producing argyria.

Neurasthenia; Its Relation to Personality.—By the term personality, J. E. Donley understands a name for a concrete, individual, living unity of thinking, feeling, willing, doing in relation with an ever-changing environment. Neurasthenia is a perturbation, disintegration, or instability of personality. It consists in a certain type of abnormality, a certain disharmony in this concrete, subject-object relation, which, as explained, is merely the philosophical way of saying that a particular living individual shows a special type of maladjustment to his environment. "Neurasthenia" and "disintegration of personality" are simply convenient ways of *naming* and *describing* this concrete process. Consequently neurasthenia has in it an element of the personal equation or the personality of the individual patient. The symptoms which are at the bottom, those of chronic fatigue, can be classified as sensory, motor, psychic, and somatic. The standpoint of the writer is that of a pragmatist, which is that method which turns away from abstraction and insufficiency, from verbal solutions, from bad *a priori* reasons, from fixed principles, closed systems, and pretended absolutes and origins. It turns toward concreteness and adequacy, toward facts, toward action, and toward power. Pragmatism is used also in a wider sense and means a certain *theory of truth*. Regarding neurasthenia psychologically as a maladaptation of a thinking, feeling, willing, acting individual to his environment, pragmatism gives a rational basis for all the procedures of psychotherapy. By its inclusion of environment as an integral part of its conception it suggests the beneficial influence of changed outward circumstances with the stimulation of diverse interests and purposes arising therefrom; for of the profound importance of environment students of comparative psychology are becoming increasingly aware. And again, insisting, as it does, that the psychological instability of neurasthenia is or may be bound up with or determined by diverse sorts of physiological change, this hypothesis makes a place for physiological chemistry, and demands a careful study and treatment of the physical substratum in every case. Finally, although the systematic study of abnormal psychology by physicians is confessedly in its infancy, none the less this study has already borne fruit of such practical value that it should not be looked upon askance, because, like every science; it deals with abstractions. For surely, abstractions are quite useful, if only they be capable of pragmatic justification.

Journal of the American Medical Association, January 4, 1908.

Headache.—From a study of 1,700 cases, in which special attention was given to the family and personal history, habits, diet, pathological and physiological conditions, etc., F. Coggeshall and W. E. MacCoy arrive at the following general conclusions: 1. A neuropathic diathesis is an essential condition of the occurrence of almost all the chronic headaches of the class discussed, the only exceptions being cases in which other causes exist to an excessive degree. 2. In the great majority there is, in addition to the neuropathic diathesis, some local irritation to the nervous system, often manifesting itself by the headache alone. 3. A minority of patients are sufferers from anemia or toxemia, in addition to the neuropathy, which may manifest itself in no other subjective symptom of importance. 4. The more marked the neuropathic tendencies, the less need be the degree of anemia or toxemia, and *vice versa*. 5. In some cases, often the most severe ones, a local irritation of the nervous system is reinforced by a toxemia. 6. There are a number of what may be called composite headaches in which two or more local irritations combine to intensify the sufferer's neuropathic tendencies and cause headache. The authors find the location of the headache the most useful single symptom for pointing out its cause. They class headaches as (1) frontal, (2) temporal, (3) occipital, (4) vertical, (5) parietal, (6) circular (band around the head), and (7) general headaches. Mixed forms, however, are not uncommon and very severe headache tends to become widely diffused. The true type in such case is often indicated by the point of greatest tenderness to pressure, or, better, by the point where it began. The local irritations are approximately, in the order of their frequency: : 1. Irritation from the eyes, (a) frontal, usually due to astigmatism; (b) occipital, often due to muscular imbalance; (c) temporal, muscular imbalance or hypermetropia; (d) or deep seated in the eyes from retinal irritability. 2. Irritation from the nose and accessory sinuses, usually frontal, more liable to be unilateral than in those due to eyestrain and confined often to a definite limited spot over the root of the nose or on one side of the forehead. These are apt to be morning headaches, and the pain is often duller and deeper seated than that from eyestrain. 3. From pelvic disorders in women; vertical when due to disease of the lining or body of the uterus and occipital when due to retrodisplacement, posterior parametritis, or ovarian disease. These headaches are practically always bilateral and may be aggravated or relieved by menstruation. 4. Gastric headaches, from indigestion, hyperacidity, hypoacidity, etc. These are practically always frontal or bilateral and more commonly located in the upper portion of the forehead than are headaches due to the eyes or nasopharynx. 5. Irritation from the teeth, especially decayed teeth in the upper jaw and the eye teeth and third molar in particular. They are usually temporal when from diseased molars and frontal when from the eye tooth. They are frequently unilateral. 6. A few cases due to the ears, sometimes to the mere presence of wax or stoppage of the Eustachian tube. They are almost the only parietal headaches from local irritation and may be unilateral or bilateral. The characteristic headache of anemia is vertical. Toxemic headaches are commonly described as of the whole upper part of the head or as bandlike or constricting. Their occurrence has frequently a relation to the time of absorption of the poison, and it may correspond with some nervous distribution, as of the occipital or upper division of the fifth. Migraine is treated of at some length, and the authors consider it practically always due to eyestrain in neuropathic individuals, but the immediate cause of the attacks may be recurring conditions of toxemia which would not have this effect in a less neurotic individual. Special directions are given as to thoroughness in the examination of the eyes in this condition, as well as regards the treatment. The authors consider the removal of local irritation the fundamental part of the treatment in headache, though general measures, tonics, hygiene, gymnastics, etc., as well as medicinal agents are not to be neglected.

Trichopathophobia.—Under this title, A. D. Mewborn includes all cases of mental worry about the hair,

on account of its loss, its color, or change of color, and its excessive or misplaced growth. Women worry most over loss of hair, and it, or the fear of it, may become a veritable obsession in neuropathic or oversensitive society women. Two cases are reported. In men the worry over loss of hair is oftenest seen in those who have acquired syphilis; this is especially seen in young men with a mild form of pityriasis, and they should be told in such a case that syphilis has probably nothing to do with their loss of hair. In such cases active local treatment will do much good. Mewborn notes the various conditions in which loss of hair occurs and gives the reasons for assuming a special toxin in the blood acting on the hair bulbs in the cases of loss of hair after the infectious disease. Sabouraud's explanation of the causation of baldness through the agency of microsporon of Malassez is given, but Mewborn considers his theory of an underlying infection with the seborrhea microbe in alopecia areata as insufficiently supported by facts and holds that in most of the cases of this affection the causes are unknown. Worry over the color of the hair is not very common, but certain shades of red sometimes give distress to certain persons. Worry over the hair growing gray sometimes troubles women and leads to the use of hair dyes to their hurt. It rarely, however, becomes a monomania. Various forms of dermatophobia occur, among which Mewborn mentions trichotillo mania, caused by prurigenous sensations in the hairy parts of the body and leading to an irresistible impulse to pull out the hair. Worry over superfluous hair growths in young women is the most serious form of trichopathophobia with which we have to deal, and all dermatologists have had such cases. In neuropathic females it may develop into insanity, and such a case is reported by the author. Precocious, perverted, or arrested activity of the sexual functions may sometimes be a cause of this condition, and there is good evidence of the influence of the ovarian secretion on the growth of hair. In conclusion, Mewborn mentions the occasional worry of young men over a deficiency of facial hair supposed to indicate a lack of virility. In such cases suggestion and counterirritation may have good effects.

Placenta Previa.—I. L. Hill considers placenta previa scarcely a rare complication among multiparæ. In 1,800 cases, 87 per cent. of them multiparæ, and averaging over four pregnancies apiece, he found the ratio to be 1 in 225. The mortality, he thinks, has been underestimated by some recent authorities, and while it may be as low under the most favorable conditions as 3 or 4 per cent., with the general average of all practitioners, he thinks it must still be as high as 8 per cent. The fetal death rate has not decreased with the maternal mortality, and is still 40 or 50 per cent. Hemorrhage occurring in the last third of the gestation period is presumptive evidence of placenta previa, and the cervix should be immediately dilated to allow of a diagnosis by the finger, and if placenta previa exists the uterus should be emptied at once. Tamponade of the cervix and vagina is a useful preliminary step. The Braxton-Hicks version controls hemorrhage well and is safest for the mother, but not so satisfactory for the child. When the condition of the cervix is such as to permit rapid delivery without serious tearing, version or forceps may be employed, packing the uterus and vagina if bleeding continues after the third stage. In a patient with long rigid cervix, complete placenta previa and viable child, and if the surroundings are favorable, cesarean section should be chosen in the interest of the child. Hill thinks that the future progress in the management of placenta previa will have to be directed to decreasing the fetal mortality.

The Lancet, December 21, 1907.

Status Lymphaticus with Reference to the Administration of Anesthetics.—A fatality from anesthesia is recorded by H. H. Rubra and A. C. Brown, whose patient was a boy of seventeen years about to undergo an operation for submucous resection of the nasal septum. The patient exhibited the lymphatic temperament, but did not seem at all nervous. The heart sounds were rather distant, but respiration with open mouth was free. The nose was almost occluded. The patient was seated in the half-upright position and an injection of cocaine and adrenalin made under the mucosa previous to giving the general anesthetic. Equal parts of ether and chloroform were administered through the Junker inhaler with the face-piece. The mixture to the amount of two drams was slowly given for eight minutes. At the end of this time the patient was apparently in good condition for going ahead with the operation, and the initial incision was made in the mucosa. He moved slightly and then it was noticed that he was very pale. Immediate measures for resuscitation were begun, but in two or three minutes the pupils dilated and remained fixed and the boy died. Autopsy showed a large thymus, somewhat enlarged spleen, and mesenteric glands, while the lymphoid nodules in the gastric mucosa were large and well marked out.

Bone Abscess Caused by an "Intermediate" Bacillus, Allied to Bacillus Typhosus.—F. G. Bushnell's patient was a man of forty-one years, admitted to hospital for acute suppurative periostitis on the front and center of the left tibia, the size of a bantam's egg, which had come on during convalescence from a fever diagnosticated as typhoid and which had been referred to the eating of shell-fish. Incision of the abscess was followed by prompt healing. Examination of the pus revealed the presence of a bacillus, which seemed intermediate between that of true typhoid and that of paratyphoid. A full account of its reaction properties is given in the original paper. The author notes that the occurrence of a bone abscess in paratyphoid fever is rare and unrecorded.

Gastric Ecchymoses, Gastrostaxis, and Simple Gastric Ulcer.—E. C. Hart considers these conditions with reference to their possible relations to the hemorrhagins and mucolysins. Gastrostaxis refers to a condition in which there is an oozing of blood from the gastric mucosa which is not obviously related to or accompanied by ulceration. The term is objectionable because it only labels a symptom, for oozing of blood from the gastric mucosa occurs in many conditions. So it is clear (1) that if there is a new disease characterized only by gastric oozing without ulceration a new name must be found for it; and (2) that the term "gastrostaxis" is only applicable as that of a symptom that is common to many diseases. The many conflicting views at present held as to the pathogeny, and possible relations of, gastric ecchymosis, gastrostaxis, and gastric ulcer may be thus epitomized. (1) Gastric ecchymosis and gastrostaxis are in no way related to each other or to gastric ulcer. (2) The cause of gastrostaxis without ulceration is quite unguessed at, the cause of ecchymosis being equally obscure. (3) The occurrence of gastric ulcer depends on a breakdown of normal immunity of mucosa against autodigestion through destruction of antipeptic bodies caused by thrombosis, embolism, necrosis, or what not. This, Weinland's theory, endows gastric mucosa with fixed antipepsin, which is supposed normally to immunize gastric epithelium against digestion. (4) Autodigestion plays no part whatever in the production of ulcer (Ball). The author then appends a long list of conditions in which gastric oozing may occur and presents a diagram showing their mutual relations. He believes that many of these are really manifestations of a general blood disease characterized by the presence in the blood of certain bodies called hemorrhagins and mucolysins. He declares that (1) no other theory as yet put forward brings into line the apparently incongruous clinical manifestations we often find, such as ulcer without hemorrhage, hemorrhage without ulcer, perforation without hemorrhage, etc.; (2) that it is useless to expect to find in the deadhouse conclusive evidence of cause and effect of hemorrhage and ulcer beyond that of extravasation; (3) that the present-day medical treatment of the conditions must be modified; and (4) that the use of surgery in combating a profound toxemia must be carefully restricted. The evidence he adduces in favor of the truth of his theory is of two kinds: (1) Direct evidence of cytolysis in man in these forms of capillary hemorrhage into and from gastric mucosa and of ulceration afforded by (*a*) blood examinations and (*b*) the remarkable results of treatment by serum and by vaccines that he has undertaken with the object of producing immunity in such cases against the specific toxins. (2) Collateral evidence of (1) cytolysis in man in other diseases characterized by gastrostaxis or other hemorrhagic fluxes or other signs of cytolysis, such as hemolysis, afforded by (*a*) blood examinations and (*b*) the encouraging results of serum and vaccine therapy that others as well as myself have undertaken with a view to the production of immunity in such cases; and (2) cytolysis in the animal kingdom afforded by (*a*) the artificial production of cytolytic phenomena in certain animals and (*b*) the establishment of immunity in such animals by (*c*) the preparation of sera and vaccines.

British Medical Journal, December 21, 1907

Tuberculosis in Childhood and Its Relation to Milk.—The paper of J. McCaw relates particularly to local conditions in his own city, Belfast. In the year 1900 26.10 per cent. of 827 bed patients in his hospital for children were tuberculous. In an experience of twenty years the author has rarely met with a case of pulmonary tuberculosis in which the decrease follows the adult type and attacks the apex of the lung. He recalls numbers of cases of children with extensive disease of the glands of the neck, in whom suppuration went on until it seemed

that the glands must have become completely eliminated, and yet in not one of them did any secondary infection of the lungs take place, and they are to-day apparently as strong, vigorous, and healthy as the best of us. How comes it, if these children were flooded with virulent human tubercle bacilli, that their lungs escaped? It seems that they were suffering from bovine tuberculosis, and that this protected them from the human type of the disease. To carry this argument to a logical conclusion: If this theory be correct, then human serum, or tuberculin R., should be beneficial when used for surgical or bovine tuberculosis; and *vice versa*, bovine serum should be beneficial in tuberculosis of human type. Much evidence could be adduced in support of this contention, and his own experience, but more especially the experience of surgeons, is that in limited tuberculous lesions of a surgical nature the injection of tuberculin R. is followed by favorable results. The author further notes that the disease appears by preference at the time of life when cow's milk is the main or almost main article of diet. It is very largely of the surgical type—that is, it is chiefly glandular and almost certainly due to the bacillus of bovine tuberculosis which has been taken into the system in food. To limit the ravages of the disease the following rules are advised: Notification of all births within twenty-four hours, complete control of the milk supply by the State medical inspector of school children and school premises, housing reform, segregation of advanced cases and compulsory notification of the disease.

Has a Purin-Free Diet any Special Therapeutic Value?—C. Watsons declares that there is no special therapeutic value in a purin-free diet in the class of cases in which such a diet is often prescribed, but that the undoubted benefit which follows in certain cases is to be explained along other lines. Purins, says the author, are constructed on the base CN, *e.g.* uric acid, xanthin, hypoxanthin, adenin, and guanin. These are present in certain articles of diet. Meat and meat extracts contain a large amount of purins; similarly, certain glandular organs, such as the pancreas and liver, are rich in purins. They are also present, though in smaller amount, in many vegetable foods—for example, beans, lentils, and oatmeal—and they are relatively abundant in some accessory articles of diet, notably tea and coffee. Purins which are taken in the diet are spoken of as exogenous purins. Purins in the tissues exist chiefly in combined form in the nuclei of cells and in the muscular tissues. Xanthin and hypoxanthin occur in muscle extracts, adenin is yielded chiefly by decomposition of nucleic acid present in thymus, and guanin is derived mainly from the pancreas. The purins in the tissues are spoken of as endogenous purins in contrast to the exogenous purins of the dietary. Purins exist in the urine chiefly in the form of uric acid, xanthin, hypoxanthin, and adenin. Roughly speaking, about one-half of the purins in the urine are derived from the ingested food (exogenous purins), the remaining half being derived from tissue metabolism (endogenous purins). The author does not believe that there is at the present time any evidence that the purin bases *per se* are in any way more intimately concerned in the actual causation of gout and gouty disorders than is their ally, uric acid, which has now by common consent been discarded. Gout is probably due to intermediate purin metabolism, arising from a defect in one or more organs, as revealed by the inability to produce the ferment or ferments required, as a result of which proper oxidation of uric acid does not occur and the latter consequently accumulates in the tissues in the manner observed in gout.

Septicemia with Interesting Reactions to Treatment and Recovery.—The patient of C. F. Fothergill was a young house surgeon who became infected at the root of a finger nail during an operation for the removal of a septic tuberculous hip. Four days later evidence of general sepsis appeared, and under gas the tissues around the nail were incised. Later it became necessary to amputate at the metacarpopharyngeal joint. Antistreptococcus serum had been freely given. Several syncope attacks came on, but the patient responded to brandy stimulation. Later it was noted that the rate of coagulability of the blood was above normal, and citric acid and lemon syrups were given freely. The patient finally recovered, though some shortness of breath on going up hill remained, probably due to some myocardial degenerative change from which recovery was incomplete. The especial features about the case are: (1) The extreme virulence of the infection. (2) The general symptoms became progressively worse until the use of the antistreptococcic serum, which almost at once acted beneficially. (3) Brandy was without doubt of great benefit when given in the two syncopal attacks, but, when the patient was given brandy four-hourly, it was found to raise both temperature and pulse, and made him more restless, and was therefore discontinued. (4) That, although the temperature and pulse had been normal or subnormal for nineteen days after the abatement of the general symptoms, yet, when the amputated finger was examined, it was found that not only had all the cartilage of the interphalangeal joints been eroded, but the bone was also eroded into the cancellous tissue, thus proving that temperature and pulse in such a case are no guide to active disease, but that the presence of continuous pain is far more important. (5) The citric acid mixture proved of wonderful efficacy in lowering the abnormally high coagulability of the blood, and seemed directly responsible for improving the character of the pus, and bringing about the rapid and thorough recovery of the wound.

Berliner klinische Wochenschrift, December 16, 1907.

The Roentgen Ray Treatment of Sweating Hands.—Kromayer says that while excessive sweating of the hands or feet can often be controlled by the use of remedial applications, such as chromic acid, formalin, hydrochloric acid, etc., there are some cases in which these fail. Sweating hands are not only a source of discomfort to their possessor, but a positive detriment from the social and business standpoint. The observation that the hands of Roentgen ray workers become very dry led him to investigate the effect of the rays in cases of this sort. While it has not been found feasible to make use of the Roentgen rays as a means of destroying superfluous hair owing to the fact that in order to secure permanent atrophy of the hair follicles too great alteration of the skin as a whole must be caused, it appears that the functional activity of the sweat glands may be abrogated without undue risk. The rays must be applied in considerable intensity, however, and in order to do this safely it is necessary to have an exact means of quantitative control. This the author has found can best be accomplished by measurement of the amount of electrical energy consumed by the tube while in operation, and he gives the details of the method in which this principle may be applied in practice. Three cases of excessive sweating of the hands cured in this way are described.

Münchener medizinische Wochenschrift, December 17, 1907.

The Treatment of Inoperable Carcinoma of the Uterus with Acetone.—Gellhorn describes the method of treating inoperable cancer of the uterus by means of applications of acetone which was devised in the St. Louis Skin and Cancer Hospital in order to overcome the fetor of the discharges, but which was found to have the additional properties of checking hemorrhage and reducing the amount of the discharge. The ulcerated surface is first thoroughly curetted, the resulting cavity is carefully dried, and one or two tablespoonfuls of pure acetone are poured into it through a cylindrical speculum, the patient's pelvis being elevated. The anesthesia is discontinued, but the patient remains in position for from fifteen minutes to half an hour. A strip of gauze is introduced into the cavity through the speculum, the patient is brought into the horizontal position, the speculum is removed, and the lower portion of the vagina and the vulva are washed with sterile water and dried. Twenty-four hours later the gauze is removed from the vagina and on the second or third day the patient leaves her bed. The after-treatment begins on the fifth day and is ambulatory. The patient lies with elevated pelvis and a cylindrical speculum is introduced into the wound cavity. It is then filled with acetone and held in position by the patient herself for about a half hour. The treatment is painless and requires no anesthesia, but in allowing the excess of fluid to escape at the expiration of the time it is necessary to protect the vulva and perineum from contact with it. The applications at first are made three times a week, but the intervals are gradually lengthened. It is advisable to repeat the curetting every one or two months. The treatment is only palliative and is not expected to influence the progress of the disease in the deep seated tissues, but it is very effective in reducing three of the most trying symptoms, the fetor, discharge, and bleeding.

Gangrene of the Scrotum Following the Application of Iodine.—Hanasiewicz says that in acute inflammations it is wiser to avoid external measures tending to induce hyperemia, as the latter, if too great, may cause such an increase of exudation as to lead to severe circulatory disturbances and perhaps gangrene in the tissues that are already the seat of injury. As an instance in point he cites a case of extensive gangrene of the scrotum due to the local application of tincture of iodine. The patient was a man of nineteen whose physician gave him the direction to paint the scrotum with iodine for an

inflammatory swelling of both testicles. The iodine was applied repeatedly with increase of the pain and swelling, so that when he came under the author's observation the scrotum was the size of a child's head and was greatly discolored. In the course of the next few days the skin of the entire anterior surface became gangrenous and sloughed away, the condition becoming so serious that for a time castration was considered advisable. The granulations became healthy, however, and the denuded area was successfully covered by means of Thiersch skin grafts.

Deutsche medizinische Wochenschrift, December 5, 12, and 19, 1907.

The Treatment of the Accessory Sinuses of the Nose.—Lublinski discusses the indications for radical operations in disease of these cavities and counsels a conservative attitude, saying that radical measures are resorted to much oftener than is really necessary. Inflammatory conditions of the antrum of Highmore ordinarily yield to internal treatment with possibly the local application of adrenalin and cocaine to relieve the swelling about the opening of the cavity and so permit free drainage. Occasionally aspiration and irrigation through the wall of the middle or inferior meatus may be necessary. In chronic inflammation due to dental caries drainage through the diseased alveolus or through the inferior meatus is indicated. The radical operation should be performed only in old neglected cases with bone caries and in which the patient wishes to obtain relief at all costs. Suppuration in the frontal sinus demands free drainage; resection of the anterior extremity of the middle turbinated body is rarely necessary, and still less so the radical operation. In chronic cases it must be performed, however, if the eye or brain are in danger. The ethmoidal and sphenoidal sinuses most frequently are involved, together with one or the other of the two large cavities. The general principles of treatment and indications for operation are the same as for these. Diseases of the sphenoidal sinus require particularly careful management, as it of all the sinuses involves the greatest risk to the eye and brain.

The Correction of Crooked Noses.—Joseph says that out of 235 nasal deformities that he has corrected by operation 23 cases were instances of lateral deviation. From the standpoint of treatment such malformations may be divided into those in which only the cartilage is at fault and those in which the bone is also involved. For the correction of the former type he has devised an operation which he terms "attraction" of the cartilage. To effect this he exposes the lateral edge of the pyriform sinus through the vestibular portion of the nostril on the side opposed to that toward which the nose inclines. The periosteum is elevated and with a bent drill a hole is bored through the edge of the bone. Two holes are also bored through the deviated cartilage and a heavy silk thread is passed through all three of these. This is tightened sufficiently and tied so as to bring the cartilage to the midline. The thread is removed at the end of three or four weeks. In cases of bony deformity a wedge-shaped piece with its apex upward is excised from the nasal process of the superior maxilla on the side opposite to the deviation. On the other side a linear incision is carried through the bone in the same direction. By pressure with the thumbs it is then possible to correct the deformity and any tendency to recurrence may be avoided by the application for a part of each day of an apparatus fixed to a circular bandage passing around the forehead and provided with pads with screw adjustment for regulating the pressure. The advantages of these operations are that they are performed intranasally so that no external scar remains, while the after treatment is shorter than when an external operation is done.

The Ophthalmo-Reaction for Tuberculosis.—Kohler tested this method on one hundred and seventy-five patients. In one hundred and sixty-nine of this number the clinical diagnosis was pulmonary tuberculosis; in five it was doubtful, and one was not tuberculous. The reaction was performed with 1, 2, and 4 per cent. solutions of old tuberculin, of which one drop was placed in the eye. Of the one hundred and sixty-nine clinically certain cases 51 per cent. of the patients reacted to the 1 per cent. solution. To the 2 per cent. solution used after the 1 per cent. had failed, 41 per cent.; to the 4 per cent. solution used after the other two had failed, 8 per cent. Of the entire number, 4.7 per cent did not give the reaction. Of the five doubtful cases, two patients reacted to the 1 per cent solution, three to the 2 per cent. solution. The patient who clinically was surely not tuberculous reacted to the 4 per cent. solution. The author considers that it may be accepted that about 95 per cent of tuberculous patients give the reaction, but that it has not yet been determined whether the method is a reliable diagnostic measure, particularly in early cases, as Schenck and Seiffert have reported positive reactions in 50 per cent. of nontuberculous cases. It is also uncertain to what extent the reaction occurs in tuberculosis of organs other than the lung.

Resection of the First Costal Cartilage for Incipient Pulmonary Tuberculosis.—Kausch reports what he believes is the first instance of resection of the first costal cartilage for pulmonary tuberculosis. The procedure is founded on the theory of Freund and Hart that in many cases of pulmonary tuberculosis there is a congenital or acquired abnormality of the first rib, which renders it less movable than normally and therefore restricts the aeration of the pulmonary apex. The patient was a woman of fifty-three years who had distinct signs of a pulmonary lesion at the right apex and gave a positive reaction on the injection of 0.003 g. of tuberculin. The first rib was exposed under ether anesthesia and two cm. of the ossified cartilage removed. After this had been done it was seen that the rib which before had been motionless now moved with respiration. The patient recovered promptly from the operation and both subjectively and objectively her condition was markedly changed for the better. The author admits that the time since the operation (three weeks) is too short to permit of any conclusions and also that the method must be tried on a considerable number of patients, but he reports the case as showing that the procedure is technically not difficult and involves no great risk to the patient.

The Serum Treatment of Tuberculosis.—Elsaesser, who has used the Marmorek serum in twenty-five cases with rather indifferent results, comes to the conclusion that treatment by inducing active immunity is to be preferred to the method of passive immunity, and he recommends for the purpose the Neutuberkulin (bacilli emulsion). He believes that in many of the cases in which success has been ascribed to the Marmorek serum, particularly in bone or joint tuberculosis with suppurating sinuses, the good effect has been due to the streptococcus antitoxins also present in the serum rather than to any bodies protective against tuberculosis. He has treated 353 patients with Neutuberkulin and he regards it as better than the Perlsucht Tuberkulin, which he has employed in fifty cases. The tuberculin treatment should be employed more widely than it is both for pulmonary tuberculosis and for the lymphatic and bone tuberculosis of children, since by this means, combined with good care, cures may be effected at home in many early cases. Hospital treatment in cities can advantageously be carried out by this method in patients in the second and third stages, if not too far advanced. In this way the sanatoriums would not be so overcrowded and a larger number of patients in the early stages could be received, while their sojourn in the institutions could also be greatly shortened. Relapses would also be lessened and readmission of the patients be rendered more infrequent.

The Treatment of Mastitis by Hyperemia.—Heinsius and Lissauer discuss this subject at length, basing their conclusions on twenty-four cases in which the method was applied with very satisfactory results. Fifteen of these were hospital patients, while the other nine were seen in private practice. The authors agree with other observers who have found the method of value, and their experience showed that early cases of mastitis could be aborted by means of the cups. The pain was relieved and the length of treatment was much reduced. If fluctuation was detected the suction was repeated once or twice before making an incision and in several instances the suppurative process receded. In the others a very small incision, 1 or 2 cm. in length, sufficed, and consequently the cosmetic results were excellent, since no serious deformity of the breast was caused. In many cases the infant could be nursed again after the inflammatory process had subsided. The only drawback to the method is the demand that it makes upon the physician's time, since it as yet seems unwise to trust its management to the nurses. A great advantage, however, is that since by its intervention mastitis is to a large extent robbed of its terrors, less opposition to nursing is likely to be encountered among the better classes.

The Use of Leeches in France.—In the course of a paper before the French Academy of Medicine, Professor Grimbert recently stated that the Central Pharmacy which dispenses supplies to the public institutions in Paris and the Department of the Seine annually furnished 12,000 leeches for use in the hospitals.

Book Reviews.

Populär Psychiatrie des Sokrates Redivivus. Gespräche über den kleinen Unverstand. Von Dr. H. Schäfer, Oberarzt a. D. der Irrenanstalt Friedrichsberg in Hamburg. Würzburg: A. Stuber's Verlag (Curt Kabitzsch), 1907.

The characters represented in the dialogues, besides Socrates, are a college professor of psychiatry, a physicist, and an asylum director. Among the thirty-six topics learnedly discussed are: Memory and judgment, insight into guilt, suicide in students, satyriasis and nymphomania, child love, perversion, who is the insane one? etc. The book is entertainingly written.

Surgery, Its Principles and Practice. By Various Authors. Edited by William Williams Keen, M.D., LL.D., Professor of the Principles of Surgery and of Clinical Surgery, Jefferson Medical College, Philadelphia. Volume II. With 572 Text Illustrations and Nine Colored Plates. Philadelphia and London: W. B. Saunders Company, 1907.

The second volume of this system continues the good impression made by the first and shows no falling off in substance or in form from the highly satisfactory matter presented in the initial installment. The first two chapters on diseases of bones and fractures are by Drs. Edward H. Nichols and Daniel N. Eisendrath respectively and comprise about a third of the volume, with 219 excellent illustrations. Both articles are extremely practical and the important subject of the treatment of fractures is discussed in an especially detailed manner. The adoption of separate sections on the surgery of the joints (Dr. Edward H. Nichols and Dr. Robert W. Lovett) and on orthopedic surgery (Dr. Robert W. Lovett), separated by two other chapters of considerable length, has involved a certain amount of arbitrary subdivision of these closely allied branches, particularly in regard to tuberculous disease of the hip and spine, but as Dr. Lovett is the author of the clinical portion of the former article and of the whole of the latter there is no overlapping and the only criticism that can be made is that convenience of reference suffers somewhat by this arrangement. Dr. Eisendrath also contributes the chapter on dislocations, and the one on the surgery of the muscles, tendons, and bursæ is by Dr. John F. Binnie. The surgery of the lymphatic system is written on by Dr. Frederic H. Gerrish and that of the skin and its appendages by Dr. John A. Fordyce. The last third of the volume is taken up by the surgery of the nervous system. The first chapter on this subject relates to the pathology of the surgical disorders of the nervous system and is by Dr. William Spiller. Dr. George Woolsey has two chapters, one on the surgery of the nerves and the other on the surgery of the spine. Neurasthenia, hysteria, and insanity as they occur in connection with trauma are considered by Dr. F. X. Dercum, and Dr. John C. DaCosta has written a chapter on surgery among the insane. As is evident from this summary of its contents, the volume includes topics of much importance and their discussion has been entrusted to competent authorities.

A Manual of Orthopedic Surgery. By Dr. Augustus Thorndike, Assistant in Orthopedics at the Harvard Medical School; Assistant Visiting Surgeon to the House of the Good Samaritan; Assistant Orthopedic Surgeon to the Children's Hospital; Fellow of the American Medical Association, the American Orthopedic Association, the Massachusetts Medical Society, etc. Illustrated. Philadelphia: P. Blakiston's Son & Co., 1907.

This admirable little book contains four hundred pages and one hundred and ninety-one illustrations. It is divided into five parts. Part I. comprises the antenatal deformities, errors of development of the skeleton or of the nervous system, fetal bone disease, accidents of birth from obstetrical paralysis or intracranial hemorrhage with spastic paralysis. Part II., deformities due to the action of external forces on growth, like weight-bearing, improper restraint from clothing, unequal or asymmetrical muscular development as in flat-foot. Part III., the diseases and injuries of the bones and joints, excepting those of the fetus. Part IV., deformities from acquired diseases of the nervous and muscular systems. Part V., a technical description of the use of plaster-of-Paris, and of the way to make, fit, and use some of the orthopedic appliances.

Studies from the Rockefeller Institute for Medical Research. Reprints. Vol. VI., 1907.

The sixth volume of reprints of articles written by workers connected with this institution opens with a description of the buildings and copies of the addresses delivered at the opening of the laboratories by Dr. C. E. Holt, Dr. W. H. Welch, President Butler of Columbia, and President Eliot of Harvard. The remainder of the volume is made up of thirty-eight reprints relating to various scientific topics.

A Text-book of Mental and Sick Nursing. Adapted for Medical Officers and Nurses in Private and Public Asylums. By Robert Jones, M.D., B.S. (Lond.), F.R.C.S. (Eng.), F.R.C.S. (Lond.), Resident Physician and Superintendent of the London County Council's Asylum, Claybury, at Woodford Bridge, Essex; Late Resident Physician and Superintendent, Earlswood Asylum, Surrey; Lecturer Upon Mental Diseases at the Westminster Hospital Medical School; Late Lecturer on Mental Diseases at the West London Post-Graduate College and the London Polyclinic; President of the Medico-Psychological Association of Great Britain and Ireland; Late President of the Section "Psychological Medicine," British Medical Association; Knight of Grace of the Order of the Hospital of St. John of Jerusalem. With an Introduction by Sir William Job Collins, M.D., M.S., B.Sc. (Lond.), F.R.C.S. (Eng.), M.P., D.L., J.C., Vice-Chancellor of the University of London; Honorary Secretary of the League of Mercy, and President of the Asylum Workers' Association. London: The Scientific Press, Limited, 1907.

The title of this little volume is descriptive of its intended use, and the comprehensive titles and positions of the writer, without personal acquaintance with him, leads the reviewer to examine it with more or less confidence as having been written with serious consideration of an important subject. The book is based on lectures delivered by the writer at Claybury Asylum, and the writer modestly asks that it may serve as a notebook during demonstrations and lectures, interleaving it for the purpose, and as an auxiliary to other text-books. The writer's apparent ideal of a mental nurse is one skilled in general nursing who has selected mental nursing as a specialty. The old classification of mental disorders is retained, but the book will be found by nurses both useful and convenient.

Manual of Physiology and Clinical Chemistry. By Elias H. Bartley, B.S., M.D., Ph.G., Professor of Chemistry, Toxicology, and Pediatrics in the Long Island College Hospital; Author of "Medical and Pharmaceutical Chemistry." Third Edition, Revised and Enlarged. With Fifty-one Illustrations. Philadelphia: P. Blakiston's Son & Co., 1907.

This little manual is intended as a guide to the ordinary clinical examination of the urine, gastric contents, blood, feces, and milk. The chapter on the urine takes up about half of the book, and is a most satisfactory piece of work; it contains all that the practitioner requires on the subject. The section on the blood is inadequate; at the present day both physicians and students require much more than is given here. With this exception the book admirably fulfills its purpose.

Treatment of the Diseases of Children. By Charles Gilmore Kerley, M.D., Professor of Diseases of Children, New York Polyclinic Medical School and Hospital; Attending Physician to the New York Infant Asylum; Attending Physician for Children, Sydenham Hospital, New York; Assistant Attending Physician to the Babies' Hospital, New York; President of the American Pediatric Society, etc. Fully Illustrated. Philadelphia and London: W. B. Saunders & Company, 1907.

The appearance of books on treatment is a healthy sign of the times; it is a necessary reaction from the therapeutic nihilism which was so threatening a decade ago. The author of the present work truthfully says: "A few great teachers of medicine have done an incalculable amount of harm by precept and example in their attitude toward therapeutics. Because they were or are unable successfully to treat disease they assume that it cannot be done. Thus therapeutic doubt, using the term therapeutics in the broad sense, has been in the past boasted of by men considered clever." The volume is written specially for the general practitioner, and is not intended either for the specialist in children's diseases or for the undergraduate student. Dr. Kerley's book contains all that a physician is likely to look for; it is practical, it embodies the results of the author's own experience, and it is so clearly and forcibly written that it is impossible for anyone not to understand the author's meaning. Among the most valuable parts of the book may be mentioned the introductory chapter, the section on nutrition and growth, in which the subject of infant feeding is fully discussed, and the chapters dealing with instructions for the summer, and drugs and drug dosage. The prescriptions are written out in full, and are unusually accurate.

Society Reports.

SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Twentieth Annual Session, Held at New Orleans, La., December 17, 18, and 19, 1907.

THE PRESIDENT, DR. HOWARD A. KELLY OF BALTIMORE, IN THE CHAIR.

Perinephritic Abscess Following Parturition.—Dr. J. SHELTON HORSLEY of Richmond, Va., reported three cases that he had operated upon, and called attention to the necessity for early diagnosis in order to give the patient the benefit of an early operation, as all statistics on this subject showed that the mortality of this disease increased as the operation was delayed. He laid stress upon the occurrence of pain in either flank a few weeks after parturition, even in cases that underwent a comparatively aseptic delivery. The bending of the body to the affected side, stiffness of the spine, slight limp in walking, and pain on pressure over the affected flank, were important early symptoms. Later there was a muscular spasm and a decided mass could be felt over the region of the kidney. Constipation was always marked, due partly to the patient's dread of muscular effort. The usual constitutional signs of sepsis appeared as the disease progressed. In all of his cases the abscess was on the right side. He attributed this to the fact that the right kidney and perinephritic tissue were lower than the left, and consequently were more likely to be injured by the bearing-down pressure of the pregnant uterus during parturition. This afforded a point of least resistance in perinephritic tissues of the right side, and germs which were absorbed by the lymphatics of the uterus might readily gain a foothold here. Treatment should follow the diagnosis at once, and should consist in a lumbar incision, as in an operation for nephrotomy, and drainage with a tube of large caliber.

Postoperative Complications in Abdominal Surgery.—Dr. CHARLES M. ROSSER of Dallas, Tex., said, among other things, that shock, whether due to basic inhibition or vasomotor paresis, could not be overcome by stimulants to an already exhausted nerve center, but position for the purpose of relieving cerebral anemia, from hemorrhage, saline solutions to enlarge the volume of the blood current, adrenalin to restore the equilibrium of the blood pressure, and morphine to give balance to the flagging vital forces, were the remedies. A rubber bandage or a suit by limiting circulatory necessity might be used either as a precaution or treatment. Post-operative peritonitis resulted from excessive trauma or infection. Drainage was the best safeguard after asepsis. If required, reopening for drainage was to be done with the least possible trauma, and minimum amount of anesthetic. Ileus or other obstruction might be treated by enema of alum solution, which reversed peristalsis and gas distention by egg turpentine emulsion thrown high up. Inhalation pneumonia suggested mouth and pharynx antisepsis, and was treated in the usual way. Hypostatic pneumonia was not so common, since physicians did not insist upon decubitus as a routine.

Some Postoperative Complications of Peritonitis.—Dr. RANDOLPH WINSLOW of Baltimore, Md., read a paper on this subject in which he reported the histories of two cases that had recently occurred in his practice. One of them was a case of appendicitis, with peritonitis, followed by intestinal obstruction from adhesions. A cure was effected by operation. The patient was a girl, twenty years of age. The second case was one of appendicitis and peritonitis followed by extensive adhesions, causing intestinal obstruction. Enterostomy was performed, followed by anastomosis, and subsequently by resection and enterorrhaphy. This patient was a male, aged nineteen. The operations were successful.

Acute Dilatation of the Stomach as a Postoperative Complication.—Dr. C. JEFF MILLER of New Orleans, La., said that among the unexpected complications that might arise after surgical operations, no condition had furnished a more distressing chapter than acute dilatation of the stomach. This complication was probably as serious as any post-operative complication that might arise. The latest statistics, gathered by Simpson, showed that of one hundred and twenty-eight cases, eighty-six died. Kayser's collection of sixty cases, quoted by Bloodgood, yielded 71 per cent. of deaths. Conner's exhaustive study of one hundred and two cases showed seventy-four deaths, or 72.5 per cent. deaths, and twenty-eight recoveries. The treatment was summed up as follows, namely, early recognition, prompt emptying and washing of the stomach, and such posture as might release a mesenteric compression. To these might be added any eliminative measure indicated, if the emunctory organs were inactive. Early diagnosis was essential to successful treatment. Judging from the cases reported in which operation was done with the idea of relieving obstruction, surgery was not encouraging. In spite of the high mortality, however, there was strong evidence to prove that many cases could be saved by prompt treatment. The author reported a case upon which he had operated successfully.

Dr. HENRY T. BYFORD of Chicago said that his experience had been that the longer the anesthesia, the less nausea there was, and the slower the patient came out from under the influence of the anesthetic, the less nausea there was. He had found it advantageous to give from one to two ounces of brandy just before giving the anesthetic, in order to diminish the amount of anesthetic necessary, as by so doing there was much less lung irritation. He had also noticed the good effect of giving an enema after operation, putting in the enema one-half or an ounce of alcohol.

Dr. GEORGE BEN JOHNSTON of Richmond, Va., could not agree with Dr. Byford that prolonged anesthesia was prudent. The smallest quantity of any anesthetic should be given, and the anesthesia should occupy as little time as possible. These conduced to the welfare of the patient As to complications, the most important thing was the prompt recognition of them. Fatalities from them occurred because they were not promptly recognized, and therefore not promptly treated. A careful study of every post-operative case would enable the experienced clinician to recognize an approaching dilatation of the stomach, and if this condition was quickly recognized and energetically treated, fully 33 per cent. of the patients would recover. The stomach should not be washed out in these cases at stated intervals, but as soon as the condition is recognized prompt lavage should be practised and continued as long as there is any indication of vomiting.

Dr. RUFUS B. HALL of Cincinnati, Ohio, in speaking of abdominal distention, referred to the value of the hypodermic use of eserine in 1-50 or 1-100 grain doses. Within forty minutes after its administration the patient will begin to pass gas. His rule had been to give patients the fiftieth of a grain under the skin, and within forty minutes, if the patient was not relieved by passing great quantities of gas, the dose was repeated. It was rare, however, that he had to give a second dose. He had used this remedy for about two years in more than thirty cases, and in only one had it failed to bring on the prompt elimination of the gas.

Dr. W. P. CARR of Washington, D. C., had had good results from eserine in a number of cases, and where he had had the stomachs of the patients washed out directly after operation and had given them a dose of eserine when they left the table, there had been very little trouble from distention by gas or in getting the bowels to move after-

wards. Washing out the stomach after an operation and giving the thirtieth of a grain of eserine on the table was very effective as a routine practice, except where the bowel was open and where one did not want to get very much peristalsis. It was only effective when there was something in the bowel. If the bowel was empty, eserine did not seem to have any effect.

Dr. Charles H. Mayo of Rochester, Minn., in referring to acute dilatation of the stomach, said there was a great amount of discomfort following operation in these cases, many of the patients dying. They died because on the second, the third, or the fourth day they showed a marked tendency to regurgitation. These patients would vomit a peculiar greenish material in large quantities. Two or three quarts might be vomited suddenly. The lower abdomen was flat, while the upper was distended. The condition would persist for four days, when there might be a profuse diarrhea. The condition could be met successfully in many cases by lavage as long as the stomach showed a tendency to refill. Many of these patients, after three or four washings of the stomach, within the third day would be entirely relieved; intestinal peristalsis would begin, and gas would escape. Some of the more severe cases could be saved by a gastrojejunostomy done between the fifth and seventh days as a secondary operation.

Dr. Herman J. Boldt of New York did not think the mortality from acute dilatation of the stomach was as high as had been quoted. However, it was a comparatively frequent and undesirable complication after abdominal section work. Whenever there was the slightest evidence of an inflammatory process in the peritoneum, salicylate of eserine did no good, so that one must be careful in the selection of his cases. Early mobility of patients would guard against some of these post-operative complications.

Dr. J. M. Mason of Birmingham, Ala., mentioned a patient who developed acute dilatation of the stomach the day following an operation, but who was entirely relieved by getting rid of the Fowler position, elevating the foot of the bed, and by resorting to lavage.

Dr. Hubert A. Royster of Raleigh, N. C., reported a case of acute dilatation of the stomach following operation for the fixation of both kidneys. The patient, however, died on the fourth day after efforts to relieve her.

Dr. John Young Brown of St. Louis, Mo., had had twenty-eight cases of diffuse peritonitis, and since he began the treatment recommended by Bond his mortality had been greatly reduced; whereas prior to that time, when he irrigated, his mortality was high. It is not so much the Fowler position as it is getting these patients to move about in bed, thus preventing the complications that were formerly observed. Of ten cases treated without the Fowler position, the results were equally as good as in those treated with it. He contended that by following a simple technique at the primary operation, complications which would otherwise arise might be prevented.

Dr. I. S. Stone of Washington, D. C., thought that after doing good surgical work the bowels of the patient should be allowed to rest. When a surgeon gave purgatives immediately after operations, he thought he defeated the very purpose he ought to attempt to accomplish. He had done quite a number of operations in the last five years, and had not had a single case of death from ileus.

Dr. Edward H. Ochsner of Chicago said the sooner surgeons learned to recognize that rest favored repair, and that motion favored adhesions, the better it would be for them and for their patients.

Transperitoneal Removal of Tumors of the Bladder.—Dr. Charles H. Mayo of Rochester, Minn., said that a large percentage of early recurrences following the removal of bladder tumors, both benign and malignant, indicated delayed operation or imperfect removal. With the increasing interest in cystoscopy, early operating was becoming more common. The ineffective operation was due, in part at least, to imperfect exposure of the operative field. The transperitoneal operation was advised in cases of large tumors, benign or malignant, of the bladder. With the patient in the Trendelenburg posture, the bladder empty, a long median incision was made over the bladder, the peritoneum opened, and the intestines walled off into the upper abdomen by large gauze pads in the operative field. The bladder was drawn up into the wound, and opened through the peritoneal covering on its posterior superior aspect. The cavity was now dried with gauze and the incision increased forward or back two or three inches, the tumor excised, and the area involved treated with the Paquelin cautery. In some cases large areas of the bladder, even two-thirds of it, might be resected. The opening was closed by catgut suture protected on its peritoneal side by a linen suture of the Cushing type. The abdominal incision was closed usually without drainage. In the after-care, repeated use of the catheter for a few days, if necessary, is preferred in uncomplicated cases.

Treatment of the Bladder after Suprapubic Cystotomy for Stone.—Dr. William S. Goldsmith of Atlanta, Ga., said the principles governing the treatment of the bladder after suprapubic cystotomy are (1) the immediate and complete closure of the bladder and abdominal wound; (2) the institution of urethral retention catheter drainage. A series of external urethrotomy cases, in which the retention catheter method was used, and following the closure of the perineal incision, convinced him of its efficiency and of the tolerance of the bladder for these unusual conditions. Perfect urethral drainage was such a necessity that failure in securing successful results was attributed to some inperfections of this important factor of treatment. Large stones could not be removed through small incisions without seriously macerating the mucous membrane and other coats and leaving a ragged, lacerated suture line altogether unsurgical in character, and encouraging tissue necrosis with eventually bad results. Upon the removal of the foreign body the wound was protected with gauze, the patient turned upon his side, and the bladder thoroughly irrigated with urethral catheter. The wound was closed tight with interrupted silk sutures, introduced down to but not including the mucous membrane. The abdominal incision was closed with small chromic catgut and cotton and collodion applied. Elaborate abdominal dressings were not used, for the reason that they served no purpose other than to interfere with the freedom of the patient in turning from side to side. In adults, and particularly men of middle age, posture was a most important detail. The ability to turn on either side and the insistence of frequent change of position stimulated urinary secretions, prevented puddling of urine, and insured a clean, collapsed cavity, which at once began a regeneration of exhausted anatomical and physiological vitality. The semi-erect, and finally the erect, position was rapidly assumed, and every effort was directed along the line of forced recuperation and rapid convalescence.

The Treatment of Fibroid Tumors of the Uterus Complicated by Pregnancy.—Dr. Lewis S. McMurtry of Louisville, Ky., alluded to the indications for surgical intervention in cases of fibromyomata complicating pregnancy, with especial reference to the time for such intervention and the plan and scope of the operative procedure in the varying conditions presented. Uterine fibromyomata were very commonly associated with sterility. The association of pregnancy with uterine fibromyomata added very materially to the dangers of this condition; that new dangers would arise from the combination of the two, and while the clinical fact that a considerable proportion of the cases came through in safety was indisputable, the mortality of the entire number of cases left to nature was

high. To illustrate the advantage of prompt operative intervention in properly selected cases, the author reported four cases. These he selected for the purpose of illustrating the multiform aspects of uterine fibromyomata complicated by pregnancy as clinically presented. His entire experience consisted of two more cases, in which operation was done in the early period of pregnancy, making six cases in all, and all recovered. While indiscriminate operation in uterine fibromyomata associated with pregnancy was not to be advised, the mortality of this condition when unaided was so great as to justify an extension of the field of operative treatment, both myomectomy and hysteromyomectomy; and every case should receive individual consideration so that a judicious selection of cases for operation might be observed.

Dr. George H. Noble of Atlanta said that where the pelvis was impacted completely, as he had seen in a number of cases, where it was impossible to make a digital examination, and the upper part of the uterus was smooth, free from the tumor, the surgeon might do one of two things, a cesarean section or a myomectomy. Since cesarean section was a simple operation, it would be desirable in the interest of the mother and of the fetus. Myomectomy could be carried much further in well selected cases.

Dr. Herman J. Boldt of New York said that a woman in about the third month of gestation consulted him as to whether or not she was pregnant. She had missed the menstrual period a couple of times, and the physician whom she first consulted informed her that she had a tumor which required immediate removal. Examination revealed a tumor in the lower anterior segment of the uterus, a fibromyoma of the interstitial variety; at the same time, she was pregnant. At the time she consulted him he advised non-interference, but that if any serious symptoms were encountered it might be necessary later to do a cesarean section in case she could not be delivered naturally. Myomectomy was decided on and done to prevent an abortion. The woman made a perfect recovery. She was now eight months pregnant.

Dr. Henry D. Fry of Washington said that in addition to the dangers mentioned by the essayist, we must recognize the increased danger in these cases from postpartum hemorrhage. The retraction of the uterus was not sufficient at the site of the placental attachment, and postpartum hermorrhage was likely to occur. Again, if the woman passed through labor satisfactorily and safely, we might have infection or necrosis of the fibroids. He had had that occur twice in his own work, where the women had been delivered safely, and their puerperium was complicated by septic fever. Supravaginal hysterectomy was done. The women got well, but in cutting down on the tumor it was found to be disintegrated and necrotic. As to the time of operation for these fibroid tumors, he thought surgeons ought to tide the cases along until the child reached the period of viability, get as near the full term of gestation as possible, and then do a cesarean section and supravaginal amputation of the uterus.

Dr. Ernest C. Lewis of New Orleans mentioned the case of a woman, five months pregnant, who had a fibroid attached to the body of the uterus and filling about one-half of the pelvis. It was not suspected until it caused pressure symptoms and pain. Her family physician sent for him, and a fibroid which could not be pushed above the brim of the pelvis was diagnosed. The cervix was pressed against the symphysis pubis. Operation was advised and consented to. The abdomen was opened, the tumor enucleated from the back portion of the uterus, the abdomen closed, the patient made an uneventful recovery, went to full term, and was delivered by her family physician with forceps. He referred to another case in which the woman was more advanced in pregnancy.

Dr. J. Wesley Bovée of Washington thought there were a great many women who would go to full term and be delivered naturally with fibroid tumors of the uterus, so that he thought we could not lay down any fast rule that would apply to every case. Each case was to be considered individually. If any operation was to be done, it was well to follow the plan Dr. Fry mentioned. The speaker was loth, however, to do a myomectomy where the growth was intimately connected with the body of the uterus, as he felt it would be apt to induce abortion. The case of Dr. Boldt impressed him as being unique, from the fact that operation was done to prevent abortion, and abortion did not occur, yet it was threatened before operation was done. As a rule, he would expect the opposite to be the case, and he doubted whether surgeons could follow Dr. Boldt's plan as a routine measure. In a number of cases he had done myomectomy without interference with pregnancy.

Dr. George Ben Johnston of Richmond believed that when fibroids could be removed early in pregnancy, this should be done, but unfortunately many of the cases did not reach the surgeon until a stage of pregnancy had been reached when this could be safely done. When a pregnancy was known to exist and was complicated by fibroids, such a patient should be closely watched, so that prompt operation might be performed, if necessary. In this way the rights of the unborn child could be respected, and it was not uncommon for such a pregnancy to go on to the period when the child was viable. He had had experience in fifteen case on which he had operated for fibroids complicating pregnancy. But his experience had been doleful in the matter of saving the children. He had not had a fatality among the mothers, but had been able to save only one child out of these fifteen cases.

The Treatment of Dislocation of the Shoulder Joint Complicated with Fracture of the Upper Extremity of the Humerus.—Dr. J. M. Mason of Birmingham, Ala., reported the case of a man who sustained a subcoracoid dislocation of both shoulders with fracture of the surgical neck of the right humerus. The left shoulder was reduced by the Kocher method, and the right was treated by arthrotomy and reduction six hours after the receipt of the injury. The fracture was wired and primary union was secured. A perfect result was obtained, and the patient had neither atrophy, pain, nor weakness in the arm, and there was no restriction of motion in any direction. A comparison of the result in the shoulder subjected to operation with the one where simple reduction of the uncomplicated dislocation was practised showed no difference. The author's conclusions were that: (1) Every dislocation of the shoulder associated with fracture of the upper extremity of the humerus was a grave injury and was likely to result in serious impairment of function if not promptly treated. (2) Every such injury should be subjected to x-ray examination for accuracy in diagnosis. (3) Gentleness should characterize all manipulative efforts at reduction, and these should not be carried to the point of bruising or lacerating the tissues. (4) Excision should only be practised where open arthrotomy has failed, where there was extensive comminution of the upper extremity of the humerus, or where, in fracture at the anatomical neck, the condition of the upper fragment did not justify a reasonable expectancy of uniting. (5) After reduction, the broken greater tuberosity should be nailed down if the case was recent, and should be removed if it caused impairment of function in an old case. (6) Failing to reduce by manipulation, immediate arthrotomy with reduction of the dislocation, followed by appropriate treatment for the fracture, had given the best results, and was the ideal method of treatment. (7) Rigid asepsis was essential in securing good results, and these operations should not be undertaken where this could not be carried out.

Fracture of the Femur in Forcible Delivery, with Presentation of Splint.—Dr. Charles R. Robins of Rich-

mond, Va., said the possibility of fracture of the femur in the various manipulations of the lower extremities in forcible delivery was mentioned in medical literature, but he had been unable to find anything on treatment. He was convinced from inquiry that such fractures were more common than the scant mention would indicate, and that successful treatment offered serious difficulties. The splint which he presented was designed for the purpose of treating such a fracture occurring in his own practice, and the result obtained was perfect. In the treatment of such a fracture it was absolutely necessary to adopt some method that would permit handling of the child for nursing without disturbing the limb, that would permit changing of napkins, that would not become soiled, and that would not excoriate the delicate skin. These indications could not be met by any of the methods in vogue for treatment in older persons. The splint he described in detail, and its application.

Some Results of the Hodgen Splint Treatment of Fractures of the Thigh as Shown by the X-Rays.—Dr. George S. Brown of Birmingham, Ala., demonstrated by means of sketches the changes he had made in the original splint of Hodgen as the latter had modified it from the old Smith's anterior splint. These changes were, first, he used one piece of cloth as a hammock to take the place of the underlapping strips of roller bandage, which were troublesome by rolling up in strings and otherwise getting out of order. Again, he had placed small tent blocks on the supporting cords by means of which the level and hang of the limb in the splint could be adjusted in a most satisfactory manner. Again, he had placed two wire loops at the distal corners of the wire frame through which were passed the traction strips of muslin which were pinned to the traction adhesive strips at the malleoli; these, being passed through these loops, were tied together across the sole of the foot, thus holding the limb firmly in the frame and doing away with the foot block which was formerly used as in the Buck's. The loops of the small suspension cords were hung upon the hook of a spring scales which in turn was hung to the sash cord that went over the pulley wheel in the ceiling. The writer claimed that while the limb was swung up from the bed and the suspension cord was at an angle, the pull was bound to be constant, and that this splint was the only apparatus so far devised that would give a constant pull. He asserted that the principle that should be followed in the treatment of fractures should be that of gradual reduction by a moderate pull steadily but constantly maintained, under which the muscles would entirely give up their resistance. Reduction under ether was unnecessary and useless, as the muscles would quickly recover their resistance and undo all that had been done in this way; that the old Hodgen splint operated on the same principle, but owing to its crudeness would not stay in order, could not be properly regulated as to the pull, and could not be properly balanced, and was not as comfortable. Buck's apparatus was painful, and for that reason the patient was constantly contriving and always succeeding in his efforts to have the weight removed long enough to allow him occasional relief from the strain on the hamstring tendons, and that this kept the muscles alive and resistant, and that as long as the muscles were alive and resistant, it was practically impossible to overcome the shortening in an oblique fracture; that with the Hodgen, the muscles were put completely out of commission in from a week to ten days. The speaker showed a number of skiagraphs taken from old patients of his, most of whom had been treated some years before the discovery of the *x*-ray. In all but two of the pictures the results were excellent, and these, he explained, had not had the advantage of proper treatment. Two pictures of fractures through the great trochanters showed union so perfect as to leave nothing more to be desired, and the same could be said of several of the shaft. In summing up, it could be said of this splint that after it was put on a limb it was well-nigh automatic in its operation. It was so comfortable that patients never objected to it in any way. It made less work for surgeons and nurses by at least 75 per cent. than any other method of treatment of these injuries, and the results were always either excellent or good.

Practical Points in the Treatment of Fractured Femur.—Dr. W. P. Carr of Washington, D. C., said that numerous surgeons had advocated wiring or some open operation on all or nearly all fractures of the femur, and claimed that perfect results could not be obtained without it. Results could be obtained in nearly all cases of simple fracture that were both functionally and anatomically perfect, if the following points were carefully observed: Extension by weight and pulley or other efficient means must be used daily. The shortening must be absolutely overcome in the first twenty-four or at most thirty-six hours, or it could never be entirely overcome. From ten to twenty-five pounds' weight would be required to do this, and great care to see that the weight was effective. Shortening is due to faulty application of the weight or too little weight. Catching of some part of the apparatus on the foot of the bed or in the mattress or bed-clothing, and slipping down in bed, are the most common defects. The traction should be applied so as to tend to lift the heel and not pull it down against the mattress, as so commonly happened. Slipping down was best prevented, not by elevating the foot of the bed, but by elevating the lower half of the mattress to an angle of 20°. In fractures just below the lesser trochanter, the elevation should be 35° or 40°, flexing the thigh to that extent, and the limb should be abducted slightly. Compound fractures should, as a rule, be wired, as the wound was usually contaminated and chances of suppuration were lessened by open operation and thorough cleansing of the parts. Children were best treated by vertical extension. All shortening could be absolutely avoided by care during the first few days. Careful measurements should be made and skiagrams, when possible. Any case not in satisfactory position at the end of a week should be wired. If simple rules of mechanics were observed, a single small loop of soft iron wire was all that would be needed to prevent shortening, lateral displacement, or rotation. Iron wire was much stronger than silver. Angular deformity must be prevented by traction, plaster-of-Paris cast, or splints, no matter what method of fastening the bones was used. Three instruments were shown that had proven very useful in resecting and wiring bone. First, a modification of Wyeth's bone saw, much simpler and more effective than Wyeth's. Second, a bone drill made like a small brace and bit, to be used in one hand while the other hand is free to hold the bone. Third, a very small thin grooved director, small enough to pass through the drill hole and guide the wire. This is very useful in passing the wire from within outward through the second fragment, especially when oozing of blood obscures the opening of the drill hole.

President's Address.—Dr. Kelly selected for his address the subject of "Art as Applied to Medicine and Surgery."

The Relaxed Knee Joint and Its Treatment.—Dr. Albert H. Freiberg of Cincinnati called attention to a group of cases involving the knee joint, which, on account of the absence of manifestations in the radiogram, the absence of any infectious element, and most often of any organic change in the joint to be appreciated by the physical examination, have for the most part been considered functional. Excluded from this consideration were the cases with knee symptoms proceeding from weak and flat-foot. The complaint of the patient in these cases was either that of joint pain largely or altogether dependent

upon function, with occasional effusion into the joint after unusual exertion, or else the occurrence of sudden attacks which were frequently very similar to those resulting from injury to the meniscus. In the latter cases there was the sudden onset of very sharp pain, so that the patient often fell. This was commonly followed by an effusion which subsided after a few days, leaving the joint apparently normal. The chief clinical character, aside from these symptoms, was atrophy of the quadriceps extensor of the thigh, and diminished power of extension of the knee consequent thereon. This atrophy was to be determined by accurate measurement with the tape line. Since the quadriceps was normally the tensor of the knee joint capsule, its relaxation permitted its falling into folds, and it was thus subjected to frequent trauma by being pinched between the femur and tibia, and the symptoms were thus explained. Villous hypertrophy might ensue in consequence of the repetition of these attacks. In all of the cases reported it was possible to determine a traumatic origin, although in several the trauma appeared to be very slight. The theory of reflex atrophy was favored rather than that of inactivity, because in several cases the limb was used without any intermission after the injury. The description of this class of cases as "relaxed knee joint" was advocated as a distinct syndrome and not simply as a feature of villous arthritis. The treatment consisted of measures to restore the volume and strength of the quadriceps, such as suitable gymnastic exercise, resisted movements, massage and electricity. Tone must be restored to the relaxed capsule by suitable local measures, such as hydrotherapy, etc. Often the return to the normal was so slow that the assumption of damage to the central nervous system seemed justified. All cases might, however, be expected to recover with proper treatment and sufficient perseverance. In summarizing, the author stated that (1) many cases of so-called functional knee symptoms were due to reflex atrophy of the quadriceps following injury; (2) the term relaxed knee joint should be reserved for such cases; (3) the injury might be so slight that its etiological relation was overlooked; (4) the atrophy following injury could in many cases not be explained by the theory of inactivity; (5) cure of these cases would be brought about by the restoration of the normal volume and strength of the quadriceps extensor; (6) in some cases recovery was so protracted as to warrant belief in material damage to the central nervous system. While in such cases endeavors were necessarily limited to treatment at the periphery, ultimate recovery might be expected to follow persevering and well-directed effort.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held December 5, 1907.

THE PRESIDENT, DR. JOHN A. WYETH, IN THE CHAIR.

Election of Officers.—*Vice-President*, Dr. Simon Flexner; *Trustee*, Dr. Arthur M. Jacobus; *Member Committee on Admissions*, Dr. Charles H. Richardson; *Member Committee on Library*, Dr. Haven Emerson.

Pathological Anatomy of Diabetes Mellitus.—Dr. EUGENE L. OPIE read this paper. He said there had been collected from the literature 188 cases of diabetes in which the pancreas exhibited lesions, which were classified as follows: Atrophy, 78; fatty change (lipomatosis save in two cases), 10; induration, 22; pancreatic calculi, 24; carcinoma, 21; cyst, 9; abscess, 6; hemorrhage, 3; necrosis, 3; fat necrosis, 2; lesions recognizable by the microscope, 7. For more than twenty-five years it had been known that the pancreas contained structures which differed from the secreting acini and had no connection with the ducts of the gland; evidence that these bodies were diseased in diabetes was advanced in 1900, and perhaps were responsible for carbohydrate metabolism disturbances. The active interest in the study of pancreatic diabetes had shown the relationship of diabetes to lesions of the pancreas and to its various histological structures and also served to explain the relationship of diabetes mellitus to certain diseases, such as arterial sclerosis and at the same time to explain the age incidence of the diabetes. In 1903 Sauerbeck collected 176 cases of diabetes in which more accurate records of the condition of the pancreas were kept and especially of the islands of Langerhans. One hundred and twelve cases had been subsequently published, and a review of these cases gave much more accurate information concerning the pathology of pancreatic diabetes than Oser's cases. There was a wide divergence of the statistics from the two sources. Interacinar pancreatitis, 123; interlobular pancreatitis, 13; lipomatosis, 18; calculi, 9; cyst, 1; carcinoma, 5; focal necrosis, 2; atrophy, 65; parenchyma normal, lesions of the islands of Langerhans, hyaline degeneration, 6; sclerosis, 4; diminished in number, 5; hypertrophied, 3; pancreas normal, 34. Even these figures failed to indicate with certainty the relative frequency of certain pancreatic changes to diabetes. Included under the designation atrophy were two wholly different conditions: First, cases in which there was gross and histological evidence that the structural elements of the gland had undergone diminution in size or in number, thus diminishing the size of the gland as a whole; there were with this condition evidences of degenerative changes in the parenchyma of the gland. Secondly, cases in which the gland was smaller than normal perhaps as the result of a congenital anomaly; the histological structure of the organ was unchanged. If the various lesions to which the pancreas was subject were reviewed, it would be found that those which destroyed the islands of Langerhans were almost constantly accompanied by diabetes. Whereas those lesions which destroyed the parenchyma and invaded the islands of Langerhans only when the changes were far advanced were in most instances unaccompanied by diabetes. Instances had been recorded in which with diabetes the islands of Langerhans had been the seat of destructive lesions, whereas the secreting parenchyma had been normal. Further evidence of the relationship of these structures to diabetes mellitus was furnished by the occurrence of hypertrophy of the islands of Langerhans in association with the disease. Facts of considerable interest were noted when the cases were grouped together according to the ages. The disease was comparatively rare in young children, and somewhat more frequent in the decade from 10 to 20 years, but during each successive decade from 20 to 70 years occurred an almost equal number of cases. It was a noteworthy fact that diabetes with normal pancreas occurred almost exclusively during the early period of life; in the second decade when diabetes was uncommon a majority of the cases exhibited no pancreatic lesion. Such cases diminished in subsequent decades and were rare after the fortieth year of life. The maximum number of the so-called cases of atrophy of the pancreas occurred during the third decade and, whereas diabetes without pancreatic lesion occurred almost wholly between the tenth and fortieth year of life, diabetes with so-called atrophy of the pancreas occurred with relatively few exceptions between the twentieth and fiftieth year. Evidence which had been cited demonstrated, he believed, that lesions of the islands of Langerhans stood in causal relation to diabetes mellitus. The table showed that diabetes occurring during the middle and later life was with few exceptions referable to a pancreatic lesion. Various types of chronic pancreatic inflammation, including the related condition known as lipomatosis or fatty infiltration, had the age incidence common to cirrhosis of the liver, chronic nephritis, and chronic inflammatory changes

in other organs. Of greater significance was the type of chronic pancreatitis which had been designated interacinal inflammation, or fine sclerosis, which had occurred in 64 of 144 instances of diabetes classified in the table of age incidence. The lesion was uncommon in early life, but after the fortieth year accompanied one-half of all cases of diabetes. This was probably referable to its relationship to general arterial sclerosis. Among the 112 cases which he had collected from recent literature, general arterial sclerosis had been present in 32 instances; sclerosis of the pancreatic arteries without note of sclerosis elsewhere had been found in 6 additional cases. Of these 38 cases, in 25 the gland had been the seat of diffuse sclerosis. Although the facts given did not admit of any definitely formed conclusions concerning the nature of all cases of diabetes, they suggested that diabetes was in most part pancreatic in origin. Nevertheless, it would not be denied that there was a group of cases in which no change in the pancreas could be found. Dr. Opie then referred to the possibility that a congenital or acquired defect of the microscopic bodies known as the islands of Langerhans might be remedied by direct transformation of groups of glandular cells into these structures; for if such transformation was possible their view of the significance of the islands must be changed. Evidence that one structure might take the form of the other was derived from two sources: (1) Transitions, it was claimed, occurred between the islands and the secreting acini. (2) By stimuli, which urge the secreting cells of the acini to discharge their contents, these cells might be forced to assume the form characteristic of those in the interacinal islands. The important discovery by Starling, namely, that an extract of the duodenal mucous membrane in weak acid contained a substance designated secretin which excited the flow of pancreatic juice, had suggested a means by which cells of the gland might be altered to assume the character of the interacinal cells. The pancreas had long occupied a unique position among the organs which were believed to produce an internal secretion. Extirpation or destruction of the pancreas produced glycosuria and other symptoms which were uninfluenced by the administration of pancreatic tissue. A century of painstaking experiment and observation had given emphasis to two noteworthy facts concerning diabetes mellitus. First, diabetes persisting until death could be produced in animals by one method alone, namely, by extirpation of the pancreas. Second, the frequent association of pancreatic disease with human diabetes, whereas the relation of this disease to changes in other organs, for example, lesions of the nervous system, was doubtful.

Symptomatology and Treatment of Diabetes Mellitus.—Dr. Frederick Beal read this paper. He said that the home of the disease was India, where ten per cent. of the total mortality of the country was due to its ravages. Thirst and dryness of the mouth, unrelieved by drinking large quantities of water, were perhaps the first symptoms as seen in America. In the tropics, however, loss of virile power and loss of knee jerk were in the majority of the cases the first symptoms. Dryness of the skin was a prominent symptom here, while in India more often perspiration occurred. The hair was dry and brittle, and the face and form became shrunken and pale, and there was a nervous, anxious expression. Emaciation was very marked and constant, especially in the younger patients. Sugar was found in the urine, sweat, and tears. Polyuria was one of the most valuable signs in this country, but in the tropics it could not be relied upon. The quantity voided was in direct ratio to the quantity of sugar in the urine. Ten to forty pints was the range of the amount passed daily. The saliva was diminished and had an acid reaction. The gums were soft and spongy, and the teeth became carious as the disease advanced. The tongue was somewhat swollen, red, and fissured, and the breath possessed an acetone odor in some cases. Constipation was the rule. Neuralgias of various nerves were frequent. Myalgia and muscular cramps occurred in many cases. Defective accommodation and retinitis of various forms occurred in twenty per cent. of the cases. Hiccough was a prominent and annoying symptom in certain cases. In a large percentage of the cases tenderness would be elicited by deep pressure over the head of the pancreas and descending colon. The urine contained sugar which varied from 1 1-2 to 8 per cent. The specific gravity was increased. The sudden disappearance of sugar from the urine was a danger signal. Sugar in the urine was always reduced in a fever patient. Pruritus, eczema, and erythema around the genitals were the commonest skin lesions, and then came furuncles and boils, while urticaria, psoriasis, gangrene, and perforating ulcers were not so common. Cancer was extremely rare in diabetes. More than one-third of all diabetics succumbed to phthisis. Gangrene of the lung was not an uncommon complication. Tabes dorsalis was a frequent forerunner of diabetes. Epilepsy might cause or result from the disease. Coma was probably the most serious complication. It occurred most frequently in those under forty. There were three forms of coma: (1) The ordinary form, beginning with headache, nausea, drowsiness, and later vomiting and unconsciousness. (2) Coma that started with collapse. (3) That form in which the symptoms resembled acute alcoholism. Death occurred usually twelve to forty-eight hours after the onset of unconsciousness. In the early stages the heart was usually dilated and hypertrophied, but in the later stages the heart's action became weak and at post mortem the organ was found small and atrophied. The pulse was usually accelerated and the tension elevated. Angina pectoris and cardiac asthma were not uncommon complications. The red blood cells were increased and sugar was increased to 0.3 and 0.5 per cent. In severe cases fat particles were found in the blood to such an extent that it assumed a pink color and deposited a creamy sediment on standing. Children of a diabetic parent or parents should partake of a diabetic diet whether they were apparently healthy or not. A non-diabetic should not sleep with a diabetic. A non-diabetic who was the husband or wife of a diabetic should only partake of a diabetic diet. Von Noorden's "yeast cure" at present claimed many adherents. The treatment to-day of diabetes mellitus, both dietetic and medicinal, was very unsatisfactory. It was generally conceded that carbohydrates should be reduced or eliminated from the diet and their place taken by albumin and fats. Each case demanded separate study to determine how much carbohydrate must be excluded from the food to stop the appearance of sugar in the urine. Among the more common substitutes for white bread, beside the gluten foods, were almond bread, almond cake, and soja bread. Flesh meat, poultry, game, fish, tongue, bacon, potted beef, preserved meats, sardines, beef tea, broth, and soups might be taken. Eggs were very useful. Whenever milk was given the urine should be watched with great care. Cream as a rule formed a diet par excellence. In fact, all fats were admissible. Nuts, cocoanuts, and almonds were useful. As a substitute for sugar diabetics could use saccharin, saxin, or dulcin. Tea, coffee, aerated waters, light wines, etc., might be allowed. One should attempt to learn the cause and then treat that cause. If there was no discoverable cause one must then treat the patient experimentally with first one drug and then another. Codeine had given better success than any other drug, and should be started in one-half grain doses and worked up to ten or fifteen grains daily. Arsenic had many advocates. The alkalies were indicated throughout the disease. Quinine, jambul, salicylate of bismuth, and many other drugs had been used with more or less good effect.

Stated Meeting, Held December 19, 1907.

The President, Dr. John A. Wyeth, in the Chair.

The Induction of Premature Labor in Amaurosis and Amblyopia, in Connection with the Albuminuria of Pregnancy.—Dr. Thomas R. Pooley read this paper. He said that twenty years ago he had published a paper on this same topic. (See Medical Record, January 28, 1888). While much was added to the original paper, nevertheless a small part of it would, of necessity, be a repetition of what had already been published. Among the indications for the induction of abortion or premature labor in the albuminuria of pregnancy, disturbances of vision had not received the attention which the great importance of the subject seemed to demand. Loss of sight might occur at any time during pregnancy or after delivery, and might recur at several successive pregnancies, but was more apt to take place in the later months. The affection of vision might last for weeks, and then, after labor, complete recovery might ensue, or the sight might become completely lost. There were two ways in which the sight might be impaired: (1) A sudden more or less transitory or complete loss of sight (uremic amaurosis) without appreciable changes in the fundus oculi; (2) a gradual failure, at first not complete loss of sight, with characteristic changes in the retina and optic nerve, which in time might lead to blindness (neuroretinitis Brightii or albuminurica). These facts having been so well established, it would seem strange that it was of comparatively recent date that the induction of premature labor, solely with the view of arresting the progress of the eye disease, had been advised, but such was the fact. From certain facts they were naturally led to consider whether it was ever justifiable or proper to provoke premature labor or abortion for the restoration or preservation of sight alone, even when other symptoms, usually recognized as sufficient cause for this procedure, might be wanting. It was the main object of this paper to discuss this very phase of the subject. From the facts presented in the paper the following conclusions were deduced: 1. That in all cases of pregnancy it was not only desirable to examine the urine from time to time, but also to examine the eyes with the ophthalmoscope, even in a routine manner, since, as was well known to oculists, a large percentage of cases having lesions of the optic nerve and retina, either had none or made no complaint of vision, but which might lead, after a long interval, through the secondary or atrophic changes, to complete blindness. It was also to be borne in mind that varying degrees of blindness, and which usually did not appear until the end of pregnancy, did not show that the retinal lesions might not already have been in existence for some time, and that the timely examination of the eyes might have saved sight and even life. Moreover, the evidences of disease of the kidneys not infrequently showed themselves in the eye before they did in the urine. 2. In uremic amaurosis, without changes in the eye visible to the ophthalmoscope, even should the usual symptoms, such as dizziness, nausea, and threatened convulsions be absent, their recurrence was soon to be feared, and labor should be induced without waiting until the life, as well as the sight of the patient, was in danger. 3. When neuroretinitis, with grave organic lesions of the optic nerve and progressive loss of vision was present in the later months of pregnancy, and the child, if not dead from the effects of the kidney disease, might be viable, it was not only justifiable, but urgently demanded, that premature labor be resorted to. If the danger of delay was such that to wait until this time would be to doom the patients to blindness, the operation should be performed even in the earlier months. 4. In those instances in which, in one pregnancy, affections of vision had occurred which had remained permanent, abortion or premature labor in the following pregnancies which occurred might be rendered necessary. 5. Prognosis as to the recovery of vision was better in cases in which chronic nephritis did not already exist. 6. The induction of premature labor or abortion, both morally and legally, was justified in order to save vision as well as life. 7. Women once having suffered loss of or impairment of vision during pregnancy should have the danger of again becoming so, and the relation of cause and effect, fully explained to both themselves and their husbands.

Dr. A. Jacobi said that the alleged indications for the induction of premature labor were numerous and among them were the death of the fetus, advanced cases of heart disease, acute tuberculosis, carcinoma, pernicious anemia, or leucocythemia, hemorrhages near the end of pregnancy, the presence of hydatid mole, acute nephritis, in which the fetus was developed poorly (although he knew of a woman who, in spite of acute exacerbations in every pregnancy, had nine healthy children in nearly thirty years), irrepressible vomiting thought to be autotoxic, incarceration of a retroflexed uterus, mental diseases, severe neuroses, etc. He said the indications were so numerous that it seemed that abortions should be very frequent. Edgar reported 2,200 hospital cases of pregnancy and the proportion was but one in 115, while Fritsch, a no meaner authority, a man of vast experience, stated that in thirty years he had had nine cases of abortion; while a young practitioner of his acquaintance had seven cases in the first year of his practice. He did not state whether this was in one of those countries where such abortions were legalized under certain circumstances, nor whether the assiduous doctor was rewarded with gratis board and lodging in a state prison. Of Edgar's nineteen cases, four were for deformity, four for eclampsia, four for albuminuria. According to the long list enumerated in most text-books on obstetrics, every one might expect to meet with proper, or improper cases, for the practice of what was called to-day by many emptying of the womb. Dr. Jacobi's obstetrical practice extended over twenty-five years and terminated thirty years ago; in both of these periods, however, he had had the opportunity to emphasize the contraindications rather than the indications. In order to be quite sure of his footing, he had looked over a number of books some days ago. He had already mentioned Edgar's work. He then called attention to De Schweinitz's book, in which it was stated that the indication for the production of abortion was the persistence of a loss of vision resulting from a previous pregnancy. After mentioning the works of other men, Dr. Jacobi said that the dangers connected with albuminuria depended upon the causes. Where it depended upon the pressure of the head on the bladder, it was innocent. But the rule was that it depended upon disturbances in the kidney. There might be simple congestion, mechanical obstruction to the circulation, and the different forms of nephritis. Amblyopia and amaurosis were caused by an albuminuric retinitis. Albuminuric retinitis might be either degenerative, in granular kidney, with vascular changes, or exudative in parenchymatous nephritis. Both of these might allow the consecutive amblyopia or amaurosis to improve. The prognosis was ominous when vision became worse in subsequent pregnancies or in marked cases of choked disk, etc. Occasionally there were cases of amblyopia caused by lead poisoning, hysteria, or reflex spasms with contractions of the blood-vessels. The latter might be improved by morphia and chloral hydrate. They could be easily diagnosticated as not belonging here, if it were not that such cases exhibited small amounts of albumin in the urine, and, on the other hand, cases of chronic contracting nephritis with very little or temporarily no albumin. Not infrequently the very worst cases of nephritis in its last stage exhibited no albumin, or so little of it that one was tempted into a treacherous

sense of security. The microscopical examination in every such case should not be omitted. At all events, no case of pregnancy after the third month should be permitted to proceed without a personal weekly examination of the urine.

Dr. E. Gruening said that the title of the paper was "The Indications for the Induction of Premature Labor for the Preservation and Restoration of Sight." Uremic amaurosis had been mentioned as one of the indications. Inasmuch as uremic amaurosis was temporary, and never caused permanent blindness, it stood to reason that for the preservation of sight uremic amaurosis could not be an indication for the induction of premature labor. The case cited by Dr. Pooley as one of uremic amaurosis could not have been one, because it ended in atrophy of the optic nerve, which was never a consequence of uremic amaurosis. He granted that uremic amaurosis was a symptom of a severe toxemia which might lead to loss of life, and therefore the indication for the induction of premature labor might be vital. It was not indicated for the preservation of sight, as this was not threatened. The same held good with regard to retinitis albuminurica of pregnancy. It had been claimed in this paper that, in this condition, the induction of premature labor was also necessary for the preservation or restoration of sight. Albuminuric retinitis, and especially the albuminuric retinitis of pregnancy, did not cause blindness. It might, however, cause death, and therefore here, too, the induction of premature labor might be imperative, not for the preservation of sight, but for the saving of life. Women who suffered from either uremic amaurosis or retinitis albuminurica might at any time have convulsions, become comatose, and die, and therefore the indication for the induction of premature labor was a life-saving measure. There was, however, one important indication for the induction of premature labor for the preservation of sight pure and simple. This was the optic neuritis of pregnancy, which threatened sight and not life. This neuritis was of toxic origin, was due to the toxemia of pregnancy, and might lead to serious deterioration of vision or even blindness, but not to loss of life. If optic neuritis had occurred in a preceding pregnancy and had impaired vision, it might lead to absolute blindness in a subsequent pregnancy.

Dr. Charles Stedman Bull, in discussing the paper of Dr. Pooley, spoke as follows: "There seems to be some doubt in the minds of certain members of the medical profession whether in the so-called nephritis of pregnancy an actual exudative retinitis ever really occurs. For instance, Krückman stated, at the twenty-fourth annual meeting of the German Ophthalmological Society, that retinitis albuminurica is never present in the kidney disease of pregnant women, if the kidneys had been normal previous to pregnancy; but in the chronic form of kidney disease complicated by pregnancy it is often present, but only when the blood pressure is increased. Rabinovitch, on the contrary, in a paper read before the Russian Ophthalmological Society in 1904, reported three cases out of a total of twenty-four cases presented, of the nephritis of pregnancy, which were accompanied by retinitis albuminurica, though the kidneys had been healthy previous to the pregnancy.

"As regards the first point emphasized in Dr. Pooley's paper, there can scarcely be any question of argument. In the retinitis albuminurica of pregnancy the prognosis as to the vision and the life of the patient depends upon the duration of gestation. With the termination of pregnancy the inflammatory process in the retina subsides, and good vision may be restored, provided the inflammatory process has not lasted long enough to cause the secondary degenerative changes in the retina. For this reason the induction of premature labor has been recommended, and if the visual disturbances appear during the first six months of pregnancy labor should be induced if the sight is to be saved. The retinitis of pregnancy presents some peculiarities. The loss of vision appears slowly and chiefly in primiparæ, and in the latter half of pregnancy. There is no contraction of the visual field, either for form or color. Sometimes complete amaurosis occurs, and this may be traced to uremia, and usually disappears. In subsequent pregnancies mild recurrences may be the rule. Retinitis gravidarum, so called, appears in the "pregnancy kidney" in from 1 to 20 per cent. of the cases. Here there is fatty degeneration of the epithelium of the uriniferous tubules, and the urine contains a large amount of albumin and many hyaline and granular casts. The pathological findings in this variety of retinitis resemble those found in other instances, but the vessels are not involved, or if they are, merely to an insignificant degree. The prognosis as to life and vision is most serious, unless premature labor is induced. If induced, there may be a complete disappearance of the retinal changes. Persistent loss of vision points to the existence of some complication, such as detachment of the retina or atrophy of the optic nerve. If labor is not induced, the majority of these women, if they live, are permanently blind. The induction of premature labor is always justifiable in order to prevent blindness or even permanent impairment of vision from retinitis albuminurica, or from the toxemia of pregnancy without the presence of exudative retinitis. It is a well-established fact that the impairment of the vision is rather due to the general retinal edema than to the patches of exudation, for the latter may remain visible for years after the disappearance of the edema and the restoration of vision. This is probably due to a degeneration of the nerve elements of the retina, probably from pressure, rather than to disease of the walls of the vessels. Schieck is probably correct in regarding retinitis albuminurica as a primary toxic destruction of the nerve elements of the retina. Another point made by Dr. Pooley should be emphasized, viz. that as the existence of kidney disease has often been first recognized by the ophthalmoscope in the determination of retinitis albuminurica, this should be one of the first means of examination employed. The natural corollary to this proposition is that the ophthalmoscope should always be employed as a matter of routine in the examination of pregnant women. I have seen many cases of chronic nephritis in which the first symptom noted by the patient was a failure of vision, which led to an ophthalmoscopic examination and the recognition of retinitis albuminurica. The eyes of pregnant women are much more likely to be affected in those cases in which chronic interstitial nephritis exists, and in these cases the retinitis albuminurica is always found. Still, acute nephritis without pre-existing kidney trouble is often developed during pregnancy, and here we are more likely to find the general retinal edema than the actual patches of exudation. In these cases, as might be predicted, the prognosis for both sight and life is much more favorable, provided premature labor be induced. In any case, should no other indications for interference arise, the steady, progressive impairment of vision will determine the time to induce premature labor. There are certain other complications of pregnancy affecting the vision which at times call for interference on the part of the physician and the induction of premature labor. One of these accidents is detachment of the retina in myopic eyes, without any positive retinitis. I recall the case of a very myopic woman who lost the sight of one eye from retinal detachment during her second pregnancy, and vision was never regained. During the sixth month of her third pregnancy the vision of the other eye became impaired and I found on examination a very marked retinal edema. I at once urged the induction of premature labor, which was consented to and brought on by her physician, and in the course of three weeks the retinal

edema disappeared and normal vision was restored. Another complication is optic neuritis, of which I have seen a number of cases, which developed before the end of the third month of pregnancy. In all of these cases there was chronic nephritis, and the induction of premature labor restored the vision to normal.

"From all that the author of the paper has considered and from our general knowledge of the subject, there can be no doubt of the justice of the following conclusions: A woman who has once suffered loss or impairment of vision during pregnancy from toxemia or actual retinitis albuminurica, should be warned of the danger of again becoming pregnant and the relation of the cause and effect should be fully explained to her and to her husband."

Dr. William H. Thomson said that many years ago he attended a case of obstetrics and once was asked to attend a young primipara. He had no suspicion of any local trouble, but he became uneasy on account of the nature of the examination of the urine every week. She never showed any albumin or casts. In spite of that there was a diminution in the amount of urine and a low specific gravity. In the course of the last month of her pregnancy she began to be nervous, had severe headaches, tachycardia, and high tension pulse. He asked an obstetrician to see her in consultation. Dr. Thomson thought the condition was dangerous and that prêmature labor should be performed, but the consultant declined to do so because there was no albumin in the urine. This was at a time when there were a great many in the profession who believed that Bright's disease and albuminuria were synonymous. Dr. Thomson was sorry that the consultant came to the conclusion he did. Five days later he was called to see the woman in severe eclampsia, in which she died. He was glad to hear so many speakers insist that the disordered kidney of pregnancy and Bright's disease were not synonymous. With regard to the etiology it should be remembered that the constitution of the mother was always profoundly affected by the chemical ingredients coming to her blood from the fetus. A very striking observation was referred to. An investigator was quite certain that the secretion of milk occurring in pregnancy was not due to any nervous element, but to some chemical ferment. Accordingly he succeeded in making an extract from rabbits (in making this extract he used forty fetuses), which, when injected into virgin rabbits resulted in every instance in causing mammary swelling and the entire list of changes that occurred in pregnancy, including the secretion of milk. If the addition to the blood from the contained fetus in the womb could bring about such striking physical and physiological changes, how likely it was that some deranged process of that kind might have a highly toxic effect upon the mother! All the early explanations of the genesis of puerperal eclampsia had never satisfied him.

Dr. Wilbur B. Marple said that no one could doubt the favorable influence which premature delivery had often had on the ocular lesions incident to the nephritis of pregnancy. Patients who had almost been blind had recovered their normal sight, and most remarkable of all was the patient of Brecht with almost total detachment in each eye, ordinarily a most hopeless condition, which became almost wholly reattached in four days after premature delivery. No careful physician of to-day neglected to make frequent urinary examinations of his pregnant patients but could one conclude that because the urine was normal the eye grounds would also be? The ocular lesion should be discovered promptly if one expected to prevent serious and possibly permanent impairment of sight. Loring was quite right when he said that the sphere of greatest usefulness, and therefore of the greatest triumph of the ophthalmoscope, would some day "be in the hands of the general physician, and especially of the obstetrician." This prediction one could make much more positively to-day when they had the electric opthalmoscope, the use of which was so much more easily learned than that of the former models. Repeated ophthalmoscopic examinations should be made of these patients during pregnancy either by the ophthalmologist or by the obstetrician himself. It was impossible to lay down any hard-and-fast rules as to the indications for premature labor in these cases. They were told, for example, that albuminuria and ocular lesions generally occurred in primiparæ; yet Silex reported a case of a woman who had gone through ten previous pregnancies and who developed visual disturbances in the eighth week of her eleventh pregnancy; although the child was born only five weeks subsequently, very serious impairment of sight resulted. Ocular troubles were said to develop more often in the last months of pregnancy; yet Loring had stated that "there are many cases in which the trouble began long before, and that the eyes if examined would have given evidence of disease before the explosion took place which cost many a mother her eyesight and oftentimes her life." Again, it was sometimes held that if in one pregnancy marked renal and ocular disease had developed, subsequent conception ought to be prevented as a matter of prophylaxis. Yet Randolph had reported two cases which showed that it was quite possible for a woman who had been nearly blind from renal retinitis to go through her next pregnancy without the slightest return of the eye trouble. Therefore the physician was between Scylla and Charybdis. Few more difficult problems confronted the practitioner than this question, as to whether or not premature delivery ought to be induced. The indication of premature labor would probably have to be resorted to to save sight (1) where extensive and serious ocular lesions, attended with marked visual impairment, manifested themselves very early in pregnancy; (2) where ocular lesions had appeared in a preceding pregnancy, especially if they had already resulted in permanent impairment of sight. When the retinal lesions were absent until the last six or seven weeks of pregnancy, they were of less grave import, unless very extensive or unless they had appeared in previous pregnancies. Loring had well said, however, that, "given a pregnant woman with loss of sight or organic lesion of the retina or optic nerve as the prominent or even sole symptom, no one could say that a series of convulsions might not set in at any moment which would carry everything before them."

Dr. Thomas R. Pooley took exception to Dr. Gruening's statement and said that cases were on record of complete amaurosis due to albuminuria, and he had had several such cases. Generally amaurosis was transitory and soon disappeared, but sometimes these cases might result in blindness. He could not accept the view that it was caused by a neuritis only. He believed there was a central focal lesion which resulted in atrophy of the optic nerve finally.

Dr. A. Ernest Gallant and Dr. George Tucker Harrison also discussed the paper.

Myasthenia of Peripheral Nervous Origin.—C. Negro has made a study of clinical cases which have convinced him that peripheral nervous troubles may cause phenomena of myasthenia. He interprets these manifestations of myasthenia as the effect of alterations of nervous nutritive processes in the peripheral motor nerves, independent of the arterial circulation, which alter the physiological conductive function of the nerves. He reports two new cases and the phenomena observed in them. From these observations he concludes that in the alterations of conduction of the peripheral motor nerves myasthenia is a somewhat rare occurrence, which is an effect of the alteration of conductibility of the voluntary stimuli on the part of the trunks of the nerves. This is the clinical expression of an exhaustion of the nervous peripheral motor system in which they are affected more quickly than normal by fatigue. The results of these observations may be of use in the diagnosis of changes in the physiological conductivity of peripheral motor neurons which precede paralysis.—*Revue Neurologique.*

ANORECTAL FISTULA.

BY CHARLES B. KELSEY, A.M., M.D.,

NEW YORK.

AN abscess which has opened into the rectum or on the cutaneous surface near the anus, and is discharging from this opening, is only potentially, not actually, a fistula. Many mistakes in treatment spring from failures to make this distinction.

A fistula implies chronicity, also induration and canalization, with shrinking of the original abscess cavity to a mere canal. Abscesses often heal spontaneously after being incised or breaking; fistulæ almost never. After an abscess has ceased to heal, when in fact it has reached a stage where spontaneous closure and repair are no longer possible, it becomes a fistula.

The old division of fistulæ into complete, blind external, and blind internal is practical and useful.

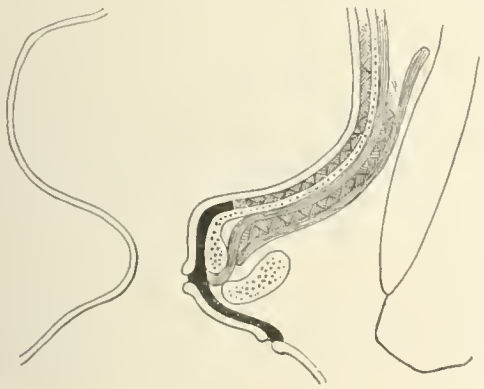

FIG. 1.—Complete fistula, showing also the submucous track running upward from the internal orifice.

These are shown in the above order in Figs. 1, 2, and 3.

Fig. 1, in addition, shows the upward or intramural track which is so often the cause of a failure to effect a cure by operation.

In the diagnosis of these varieties from each other a probe will not always be found sufficient. The blind internal form is difficult to examine by probing, and in all but the straight and simple varieties of the complete and blind external the track is apt to be too tortuous to admit of the passage of a probe.

Should it be deemed necessary to make the diagnosis absolutely before operating, the distention of the track with milk injected through a small syringe, which completely plugs the orifice into which it is introduced, is the favorite method.

The direction and extent of the track can often be made out more positively by gentle digital examination than by a probe. The track is hard, cordlike, and can often be felt as such under the skin and mucosa for its entire extent better without the previous introduction of a probe than with.

Fistulæ, like the abscesses which cause them, are best divided into superficial and deep, or those below and those above the levator ani muscle and the pelvic fascia. The former constitute the vast major-

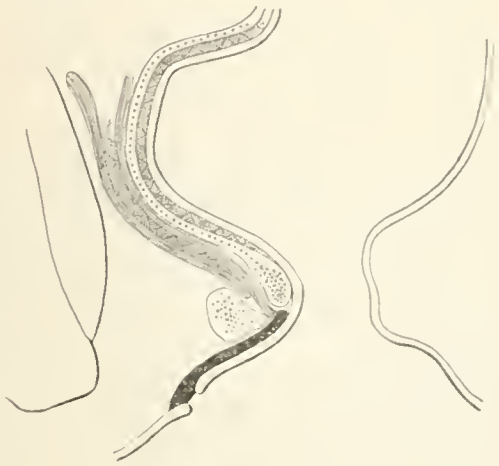

FIG. 2.—Blind external fistula.

ity; the latter are rare, much more serious, often incurable.

Superficial Fistulæ.—These are either subcutaneous, submucous, submuco-cutaneous, or ischiorectal, as were the abscesses of which they are the remains. The subcutaneous and submucous are sufficiently well indicated in the cuts. It will be seen that in all of them the internal orifice, when there is one, is just between the internal and external sphincters, and that the tracks are just under the surface, as their names indicate.

FIG. 3.—Blind internal fistula (schematic).

In Fig. 4 is shown a complete fistula from an ischiorectal abscess—still, though, much deeper than the last, to be classified among the superficial varieties. It will be seen that the internal orifice is much higher in the gut, that it is above the internal

sphincter, instead of below, and that a finger in the bowel will show a considerable mass of tissue between it and a probe passed along the track. It should also be noted that the track has not perforated the levator, but passed just below its blending with the rectum.

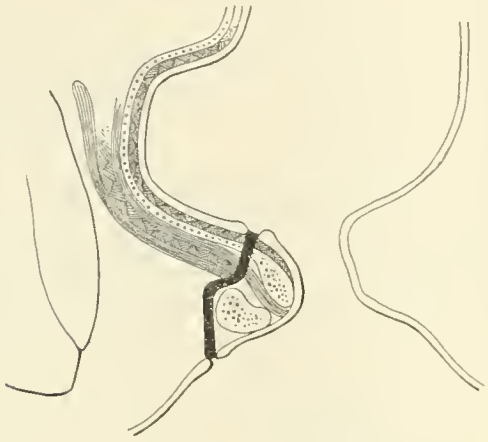

Fig. 4.—Fistula from ischiorectal abscess.

All of these varieties of superficial disease may be modified in almost countless ways. There may be two or three external openings, in fact twenty. There may be more than one internal opening, and tracks may run in any and every direction; but they all come under the same general class and the same general rules of treatment, no matter how great their complexity.

Treatment of Superficial Fistulæ.—Much thought and effort have been devoted to attempts to secure healing of these long ulcers with infiltrated bases without cutting them open, but with no great success. Very free cauterization with destructive fluids as nitrate of silver or caustic potash, combined with drainage will, however, be occasionally successful, and this treatment may properly be applied to deep tracks passing outside of the internal sphincter, the division of which by the knife is liable to be followed by incontinence.

Although nothing can be promised the patient from this method, it sometimes results very satisfactorily. Fluids used in this way are much more efficient than solids, and the method should always provide for free discharge from the cutaneous opening by slight incisions under eucaine if necessary.

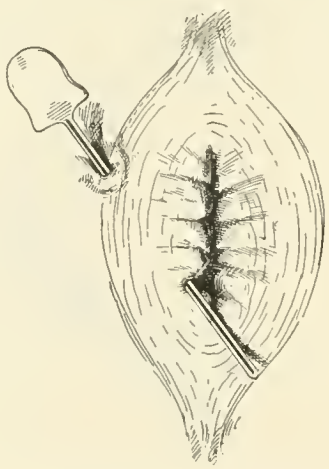

Fig. 5.—Improper division of sphincters.

When this method has been thoroughly tried and failed, I know of no other which is worth trying, though in one case of extensive inoperable disease I had great hopes for a time from powerful applications of electricity by high-frequency currents passed directly into the sinuses. The result was, however, *nil*.

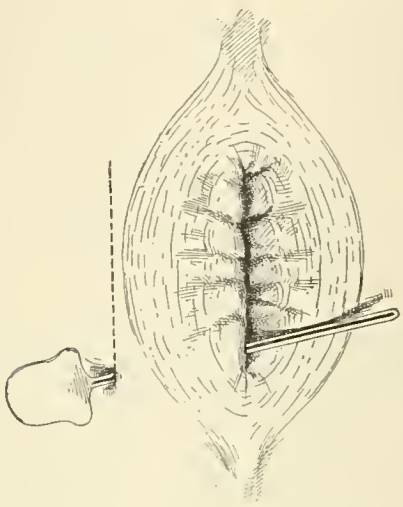

Fig. 6.—Correct division of sphincters.

The question next arises whether all, even superficial, fistulæ should be cut, even when such an operation involves no more than the usual surgical risk, and I would answer, by no means.

Of course, in patients near their end from constitutional disease, nobody would care to operate. Again, even in patients in good health the disease may be so extensive that its cure may amount to a major surgical operation, and the patient may succumb. But the question which is always before both surgeon and the patient with one or more deep tracks, is the possibility of resulting incontinence from incision of the muscles at one or more points. Much may be done by a skillful surgeon to avoid this, as we shall show, but it is well to remember that a patient with a fistula, and especially one of the blind internal variety, may be much more comfortable than after he has been cured and rendered incontinent.

When it comes to the question of operation there are several methods which need not detain us, though much space is given to their consideration in the text-books. These are dissecting out the fistulous track and its surrounding indurated base; incision by elastic ligature, and incision by silk ligature. The two last are unsurgical methods of making incisions, and may as well be delegated to the limbo

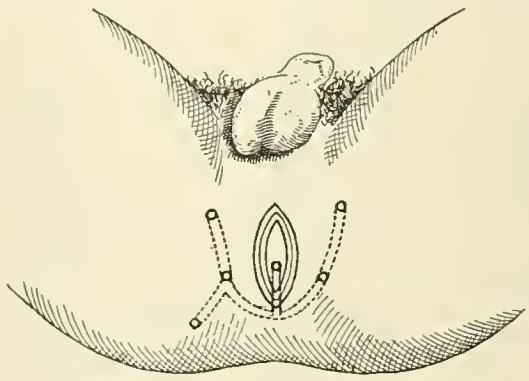

Fig. 7.—Complicated fistula with several external and one internal opening.

of past history in all ordinary cases. The former is unnecessary, and, if combined with the attempt to secure union by first intention, is almost invariably a failure.

Reduced, then, as we are to cutting with a scalpel, which is really a fairly good way of cutting when cutting is to be done, one more question has arisen in practice, and that is whether to do all the cutting that is to be done at one time and under general anesthesia when necessary, or to do it by fractions of an inch under local anesthesia. To a surgeon this may seem ridiculous, and in most cases it is; but it is not so to the patient. To him, cutting by inches under local anesthesia does not mean hospital, ether, or an operation.

While it is true that many of the simple subcutaneous and submucous fistulæ may be cut successfully under eucaine, and I have done much of this work in the office very satisfactorily, when it comes to cutting a horseshoe track in this way by *forty-four* partial incisions, we have passed far beyond the legitimate scope of a legitimate method of treatment. I have such a case now suffering from incontinence, and complaining rather bitterly of the result which was obtained by the chief exponent of this method in New York.

The first rule for avoiding incontinence is to cut

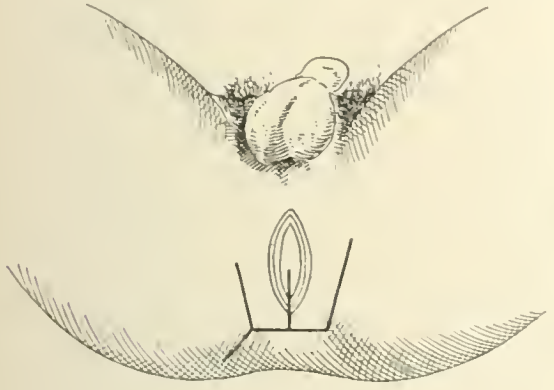

Fig. 8.—Showing how fistula such as Fig. 7 may be cured by single division of sphincters.

the muscles as little as possible, and to cut them directly across the course of the fibers, not diagonally. How this may be done in a simple case is shown in Figs. 5 and 6.

Take, for example, the ordinary form of posterior horseshoe track shown in Fig. 7, where we have five external openings and one internal.

This may be divided completely along the lines shown in Fig. 8 without resulting muscular impairment, while if done along the lines in Fig. 9 incontinence is certain.

This condition must not be mistaken for that shown in Fig. 10, where we have three external openings and three internal ones, and any cutting of the external openings 1, 2, and 3 into the internal opening 4 is bound to be followed by failure. I have just such a case now under treatment, where an operation under cocaine was followed by bitter disappointment to both surgeon and patient—the tracks from 2 to 3, from 1 to 3, and 3 to 4 being cut, while the tracks from 1 to 5 and from 2 to 6 were left entirely untreated, and requiring a second operation.

Almost a similar condition is shown in Fig. 11, where we have three internal openings and only one external. Both of these forms will require three divisions of the sphincters, and subsequent incontinence may be predicted with certainty. The principle is plain. The entire track and all its branches must be laid open.

The case shown in Fig. 12 had six openings, three external and three internal only, four of

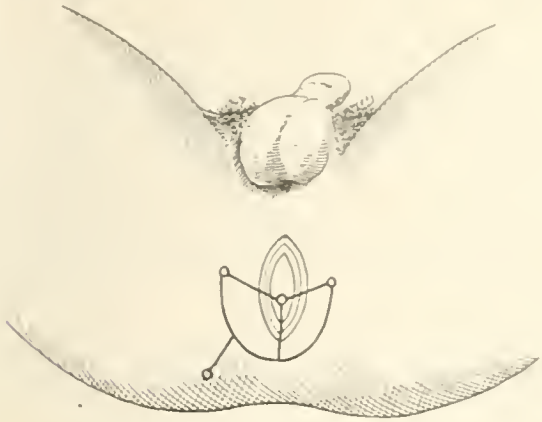

Fig. 9.—Improper division of fistula shown in Fig. 7.

which were cut to avoid a double division of the whole perineum, Fig. 13. The remainder of the tracks were thoroughly curetted and cauterized at the time of the operation, and, being straight and short, the result was fortunately satisfactory.

In all of these cases of abscess or fistula resulting from the glands of Bartholin, in addition to opening the abscess or cutting the fistula, the gland should be extirpated to be sure of effecting a cure.

We have given these details to show that by careful examination before operation it is generally possible to give a pretty accurate prognosis as to the question of incontinence. The great uncertainty, however, comes from the fact that the exact conditions are much more apt to become evident when the patient is under ether and the operation has begun than by any previous examination in the office. And this will always be the great practical objection to office operations under local anesthesia. Until the cutting has actually begun its extent is often uncertain, and a thing which looks simple becomes complicated, so that instead of a simple condition we find a very complex one, and instead of a single incision forty-four may be necessary. Only

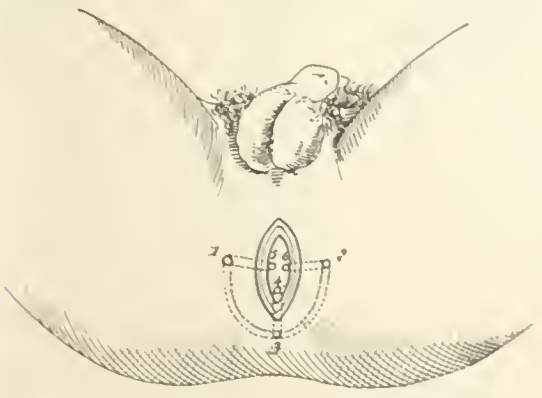

Fig. 10.—Fistula with three external and three internal openings

the general rules can be marked out as we have tried to indicate, and one very practical one is that a fistulous indurated ulcer can seldom be cured by cutting one end of it and leaving the other; nor will any drainage established in this manner generally be of much benefit.

With the patients under general anesthesia and in a good light, it is not necessary to spend much time in probing to find the exact extent of the trouble before beginning to cut. The moment the external orifice is laid open the course of the track becomes evident, and it is to be followed in all its ramifications, unless the hope of cure is abandoned after the operation has begun.

The worst results come from the prevalent method of cutting only after a director has been entered at the external orifice, pushed along with all the force necessary, and made to emerge at the internal orifice. Then all the tissue over the director is cut and often much harm is done. A director often cannot be passed from one opening to the other without either a false passage through healthy tissue or great distortion of the parts. It should not be tried. Pass the director along the track an inch or even half an inch and cut, then follow the track with the director another inch and cut again. In this way the end will finally be reached, and often as well without any director as with one.

Tuberculous Fistula.—There is generally something quite diagnostic in the appearance of a tuberculous fistula, although the diagnosis can only be made with certainty by the proper examination of

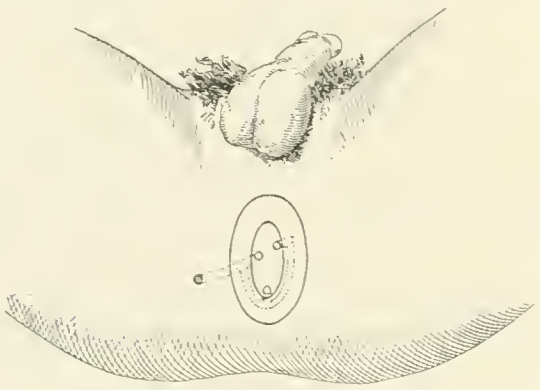

Fig. 11.—Fistula with one external and three internal openings.

the discharge. The openings, internal or external, are usually large, the tissue surrounding them are undermined, the skin is violet-colored and unhealthy, and apt to be studded with tuberculous nodules which have broken down; the discharge is saneous and unhealthy, and the whole appearance is that of sluggish ulcer showing no reparative action.

Time was when to say that a fistula was tuberculous was equivalent to saying it was incurable, but that is past. The treatment is the same as with simple inflammatory ones, only more radical, and directed primarily to the destruction of the tuberculous deposit. Simple incisions are therefore not to be relied upon. They must be combined with thorough cauterization (preferably the actual cautery) and with *reclage*, and these means may have to be repeated again and again. The general health must also be improved in every possible way.

As showing what may be done with patients under the best advantages, I have been greatly pleased with the result obtained in one of my own cases. The young lady had been in a private room in one of our city hospitals for many months, and had submitted to several operations without benefit, being finally allowed to go as incurable and tubercular. There was no other evidence of tuberculosis, but the perineum had been pretty much destroyed by cutting and burrowing, and there was apparently no healthy reparative action. She was under my care for nearly one year, and in hospital three times for cauterization and curettage. During all that time the ulcer was dressed by myself, and at every appearance of anything like a new tubercle or a fresh pocket, the galvano-cautery point

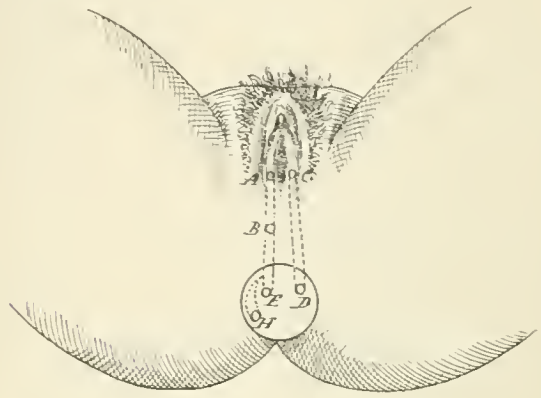

Fig. 12.—Complicated recto-labial fistula.

was applied under cocaine. She finally left me for a trip in Europe to be gone a few months, and as the ulcer was then only very nearly healed and she stayed a year, and meanwhile married, I expected upon her return to find the condition much as when she went, if not worse. Examination, however, showed every trace of the ulcer soundly cicatrized, her general health perfect, and we are now considering a plastic operation for repairing the perineum.

This result could only have been obtained under the most favorable conditions, but given those conditions, it is a safe rule of practice that tubercular fistula, even where there is slight tuberculous deposit elsewhere, may be cured as other fistula may.

Incontinence.—The restoration of the sphincter muscles to their function after they have been cut in an operation for fistula, opens up a much more delicate and interesting field of surgery than the mere cutting of a fistula.

Incontinence is a relative term, and though a patient may have lost absolutely the power to prevent a movement of the bowels at will, he may never be conscious of the loss unless he has a diarrhea. The desire for defecation, as dwelt upon by myself years

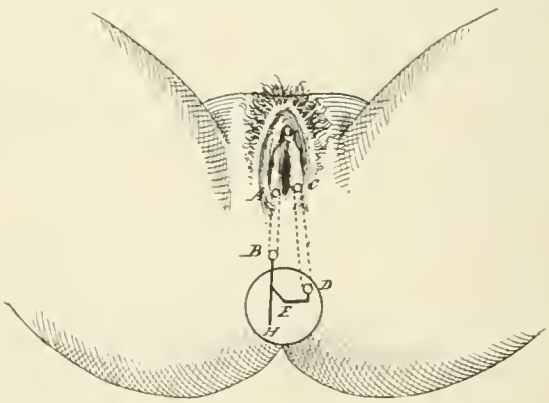

Fig. 13.—Incisions made in fistula shown in Fig. 12.

ago, is caused by reflex nervous influence. When the rectum is filled the patient responds to these reflex sensations, and, sphincter or no sphincter, the result with a natural formed passage is much the same. But, given a diarrhea, a distance from the commode, and the necessity of postponing the act,

and the utter inability to do so, becomes painfully manifest. In the earlier editions of my book is pictured an old case of fistula in which, as a result of cicatrization, the anus and rectum for at least four inches were converted into a fibrous, open, non-contractile canal, one inch in diameter through its

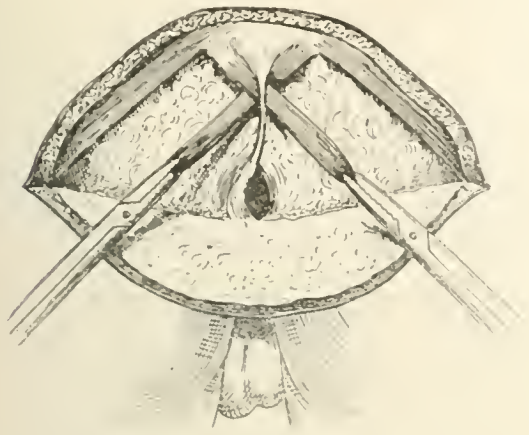

Fig. 14.—Operation for incontinence.

entire length, and yet this man, a big, healthy laborer, with the appetite and digestion of an ostrich, assured me that he had perfect control and never had the least trouble. Nor had he, but he never remembered having had a diarrhea.

In contrast to this I have known a delicate lady, confined to her room and bathroom twelve years as a chronic invalid, by the simple fear of accidents which occasionally happened as the result of a single slight incision through the sphincters. One attempt had been made at repair, which failed, and the case was then pronounced incurable without any examination by a general practitioner of national reputation. At first sight the defect was hard to locate, the skin having healed over it so as to conceal the break in the continuity of the muscle. But when this was found by the depression under the skin, laid open, the edges of the muscle freshened and sutured exactly as is done every day in any old case of laceration of the perineum from childbirth, the cure was perfect.

This, then is the operation of choice—expose the divided ends of the muscle and suture them carefully and thoroughly with every precaution for obtaining primary union. Should there be a double defect in the muscle, operate on each separately after an interval.

Should this method fail, but it will not often fail to give great relief, if not a positive cure, we are reduced to plastic operations, by which other muscular fibers are transplanted to take the place of the sphincters—generally strips from the glutei. Of all these, Chetwood's promises the best results and is simplest in performance.

A skin flap, as shown in Fig. 14, is turned forward, the fat dissected away till the edges of the gluteus are exposed, and a bundle of its fibers about a quarter of an inch in thickness is separated from each muscle cut below and left attached at the coccyx. These bands are crossed and passed under the ligamentous tissue connecting the tip of the coccyx with the anus. They are then made to encircle the anus, and the free ends are sutured under the skin in front of it. A deep tension suture is a wise precaution, and the operative field is again covered by its skin flap, Fig. 15.

Pelvic Fistulæ.—In fistulæ of the pelvirectal space we encounter many much more serious conditions. These have for their origin the same causes as the abscesses from which they originate, viz., inflammation of ovaries, tubes, or ligaments in women; of the prostate, seminal vesicles, or urethra in men; acute inflammation of hemorrhoids; diseased bone in or near the pelvis, and chronic ulcerative disease of the rectum, as stricture or cancer.

Deep pelvic fistula, like the superficial, may be either blind external, blind internal, or complete, and are often multiple, with the openings at a long distance from the primary focus, extending far out upon the buttock or thigh, or upward upon the abdominal wall.

The diagnosis is not difficult, for a long probe or uterine sound introduced into the cutaneous orifice leads not into the rectum, but parallel with it, or even away from it, till lost somewhere in the pelvis.

Treatment of Deep Pelvic Fistula.—It is evident that this form of disease cannot be treated as the superficial would be. All operative interference is often contraindicated, especially in the variety with blind internal orifice opening into the rectum some inches above the anus, and in the varieties due to old organic disease of the rectum.

Where communications exist between the rectum and genital organs in the female, laparotomy is generally necessary to clean out the original abscess, and the opening into the gut may be closed at the same time. Every surgeon knows the additional danger of laparotomy for pelvic abscess where this complication is present.

In the male, where rectogenital communication has been established, or where as a result of old stricture of the urethra abscess or extravasation has occurred and tracks have formed after opening far away from the original site, colostomy may be the only resource. Under such circumstances the artificial anus should be of the temporary or provisional type, made with as little destruction of the intestinal wall as possible, and with the definite provision

Fig. 15.—Operation for incontinence

for future closure by plastic operation without opening the peritoneum, should it be found effectual in curing the fistula. That it will often accomplish this end, and in cases where all other means have failed, I have more than once proved by happy experience.

In one case in which I operated years ago for Dr. Bangs, these openings, discharging both feces and urine, were so numerous, and the tracks so

long, that any local interference was out of the question, and a perfect result followed a temporary colostomy. When all the sinuses had closed spontaneously we offered to close the artificial anus, as the rectum had regained nearly its normal condition, but the man declined the operation, being very well satisfied as he was, and experiencing very little trouble from the artificial opening.

The artificial anus in these cases should, as I have said, always be made so as to admit of subsequent closure by a plastic operation without opening the peritoneal cavity; and I would suggest that the great value of this procedure in the treatment of many varieties of fecal fistula has not as yet been thoroughly recognized by the profession. Many of the rectovaginal, rectourethral, and rectovesical forms, as well as those simple ones opening on the abdominal wall, which have resisted the most careful and elaborate plastic operations, will, I believe, close spontaneously or after a little freshening of the edges, when once the contact with the feces is prevented by temporarily diverting their course.

As showing what may be necessary in the way of treatment to cure these deep pelvic fistulæ, the following case may not be without interest:

Not very long ago a woman was brought to me from the West who had undergone fourteen operations and examinations under ether for fistula without benefit. The external opening of the supposed rectal fistula was not more than an inch from the anus posteriorly, and into this a probe passed somewhere into the pelvis about eight inches, but just where could not be discovered. By pelvic examination an old cellulitis on the left side could be distinctly felt, and my diagnosis was that this was the source of the abscess and origin of the track. Posterior colpotomy was therefore my first attack, but no pus and no upper end of a long uterine sound passed upward from the skin opening could be found. The incision was plugged with gauze and the abdomen opened again in front for more thorough search, with exactly the same result—only the evidences of an old inflammation around the ovary, but no pus and no probe. This incision was closed, the other being left open for drainage. The woman was then turned upon her face, and I started deliberately to follow that uterine sound with a knife from the skin as far into the pelvis as it might lead. I did follow it into the body of the sacrum on the posterior surface and up to the promontory, which was carious and filled with pus, and a good prognosis as to result and permanent cure was given. The patient did not do well, however. In fact, she steadily grew worse in general condition and became markedly septic, and I had just about given up the hope of saving her life when, more by accident than anything else, I discovered a painful tumor near the spine in the upper lumbar region. There had been no complaint of this, the patient being delirious and thoroughly septic, but that it was a huge metastatic abscess in the loin a deep incision soon proved.

From this time on recovery was uninterrupted. Many spiculæ of bone came away from the sacrum, and finally a long, thin fragment, four inches in length, after which all sinuses closed. The patient, when last heard from, had been free from all signs of the disease four years.

In the simpler forms, where a deep fistula five or six inches long, has formed with external and internal openings, and where much tissue must be cut to hope for cure with the almost certain result of incontinence, it is often better to abstain from operation, lest matters be made worse, instead of better. But should cutting be decided upon, provision must be made for severe hemorrhage. Some of these tracks have been divided with an elastic ligature, and it is just in these cases that this method of division finds its chief applicability.

As a rule, it is best to thoroughly open the cutaneous orifice, so that free access to the whole track can be secured. Then use the sharp curette thoroughly, and after this free application of saturated solution of nitrate of silver to every part, and keep the external opening free for subsequent drainage.

When this is done thoroughly as a surgical operation under general anesthesia, a cure will sometimes be obtained. When it is done in a pottering, half-hearted way in one's office, a little at a time and often repeated, failure may be expected. From this method I have had a few cases result most satisfactorily. One notable one was in a young man with a deep pelvic track, the outer two inches of which had been unsuccessfully cut several times, so that he refused further treatment by operation, and in whom the internal opening was above the reach of the finger. The agent used in his case was very strong tincture of iodine injected through a fine syringe, so as to reach and distend every part of the track. Two injections resulted in a cure.

SCHLÖSSER'S ALCOHOL INJECTIONS FOR FACIAL NEURALGIA.

SIXTEEN MONTHS' EXPERIENCE WITH 55 CASES; THREE FAILURES.*

By OTTO KILIANI, M.D.,

NEW YORK.

On December 7, 1906, I read before the Surgical Section of the Academy of Medicine a paper† on Schlösser's treatment for Trigeminal Neuralgia. I now wish to report my personal experiences of the last sixteen months with this method. Before I enter into my statistics, it may be necessary to shortly describe the idea, as well as the technique of the treatment.

Within the last six years quite a literature has developed upon the injection method as a treatment for tic douloureux. A great many different remedies have been tried for injection, as, stovain, cocaine, chloroform, air, nitrate of silver, antipyrin, and osmic acid. The last named has probably been used most extensively. All these substances were injected *loco dolenti*, usually simply subcutaneously at the seat of pain.

Schlösser was the first to make 80 per cent. alcohol injections either into the foramen through which the respective branch emerges into the face, or, if necessary, into the foramen ovale and rotundum.

As it is impossible to demonstrate to a large meeting the technique employed, it must suffice to say that all the foramina named can be reached with a needle in an experienced hand, safely and with certainty. The amount of alcohol injected is about 2 c.c.

Since September 1, 1906, I have seen and treated by injection 55 cases of facial neuralgia. I have learned a great deal about this disease and its peculiarities, but have to confine myself to-night strictly to the alcohol injections.

*Read before the Medical Society of the County of New York at its stated meeting, December 23, 1907.

†Published in the Medical Record, December 29, 1906.

As to the branches affected, the cases were divided as follows:

I. Branch alone affected	0 cases
II. Branch alone affected	13 cases
III. Branch alone affected	0 cases
I. and II. Branch affected	4 cases
I., II. and III. Branch affected	3 cases
II. and III. Branch affected	35 cases
	55 cases

In five cases the patients located the pain only in the II. branch and did not find out until that one was successfully treated that the III. branch was affected too, only in a lesser degree. In one case the occipital nerve was also affected, and successfully treated.

The neuralgia had been established for from six months to twenty years, namely:

Under one year	1 case
One to two years	7 cases
Two to five years	30 cases
Five to ten years	10 cases
Ten to twenty years	7 cases

As to the age of the afflicted patients, there was

22 years	1 case
30 to 40 years	2 cases
40 to 50 years	16 cases
50 to 60 years	28 cases
60 to 77 years	8 cases
	55 cases

There were 35 men against 20 women, that is, a proportion of 7 to 4.

I do not wish to give a percentage statistic of the occupation, because it would be without any value, if we do not know the relative proportion of the occupations themselves from the stand of political economy. But I can say that the rich and the poor are represented, the learned professions as well as the farmer and workman; among women, the maid and hard-working housewife as well as the stately lady of leisure.

Neurasthenic or neurotic predisposition could be proven in 10 cases. Of other possibly predisposing diseases, such as gout and diabetes, we find 9 cases.

As immediate causes are given: Shock (explosion), 1; exposure to cold and water, 3; grippe, 7; no cause given, 44.

Side affected: Left, 35 cases; right, 18; both, 2.

All patients had been treated before with internal medicaments, sedatives, external applications, as salves, etc., electricity, osteopathy, and what not. One case was treated with *x*-rays. Thirty-seven patients had teeth extracted, some, all of them. Peripheral operations (resection) had been done on 22 patients, namely, I. branch, 4 cases; II., 6; II. and III., 6; III., 6.

In four patients the Gasserian ganglion had been removed by the Krause-Hartley method. One patient had as many as seven operations performed on him.

The frequency of attacks varied from one in three days to one every few minutes. Although the resistance and self-control of patients doubtless varies greatly, the violence of the attacks is not the same in all patients.

I come now to the injections and their immediate and remote results. In all cases I have made peripheral injections first, even if I expected that I might have to inject into the ganglion. All the injections are done without any narcosis or local anesthesia. The insertion of the blunt needle (Schlösser's needles are of rather heavy tubing beveled off at 45 degrees to avoid any piercing effect of the needle) into the foramen is rather painful; the slow injection of the alcohol somewhat more so, but not beyond the endurance of the patients, who are accustomed to a great deal of pain. Every successful injection must produce, within a few minutes, a burning or benumbing sensation within the region of the nerve injected. This develops, sometimes after a severe period of pain for two or three hours, into a more or less pronounced anesthesia. Any of the three peripheral injections produces a swelling, which in the first and second branch results in edema of the eyelids, and in the third branch sometimes in a slight trismus. Nearly every injection into the second branch through the foramen infraorbitale produces a slight facial paresis, owing to the connecting branch of the ganglion sphenopalatinum with the loop of the facial nerve. This paresis disappears within a period of from three days to two weeks. To reach the part of the II. branch which supplies the roof of the mouth and the roots of the rear teeth, it is sometimes necessary to inject into the ganglion sphenopalatinum, a procedure which I have ventured only lately, as I was afraid of the entrance of the alcohol through the outer fissure into the orbita, with its possible disastrous results on the eye-muscles or even the optic nerve. But a carefully slow instillation has prevented any trouble so far.

Injection through the foramen ovale or rotundum into the root of the II. or III. branch, or the ganglion itself, must at once produce, if carried out properly, a complete anesthesia in the region of the nerve attacked. Only if gasserectomy has been done before, the effect may be delayed, owing to the scar-tissue resulting from the former operation.

The number of injections necessary to produce freedom from pain ranged with the I. branch from 2 to 4; with the II., from 4 to 16; with the III., from 2 to 5. I may add here that in those cases, where so many peripheral injections were necessary, one or two injections into the ganglion would have achieved the same result. The time occupied to get the patients free of pain varied from three days to five weeks.

The diagnosis of facial neuralgia rests to a large degree upon the statements of the patients, although a typical severe paroxysm cannot be mistaken for anything else. It is therefore only fair to pronounce a patient cured for the time being, only if the patient says so himself or herself.

Of the 55 cases treated, I have been informed by three patients that they considered the treatment a failure, and I therefore accept them as such, according to the above reasoning. The worst experience I had with a patient kindly submitted to me by Dr. Dana, a woman 65 years of age, afflicted with neuralgia of the II. and III. branch. After the third injection into the II. branch, the patient showed a typical paresis of the oculomotorius nerve,* producing ptosis, squinting and double vision, a condition which lasted, according to my information, nearly four weeks. When I saw the patient last, she was, according to her own and her family's statement, free of pain; but she stated later to Dr. Dana that she was as badly off as before. As I have not had a chance to re-examine the patient, I accept her statement and count her as a failure.

The second patient who considers the treatment a failure, a woman of 34, a rather unruly patient, left after four weeks of treatment for her home in

*This being the only surgical accident I had.

Virginia. Six months afterwards, examined by Dr. George W. Jacoby, the patient showed complete anesthesia in the II. branch treated. When her attention was called to the fact that she could not very well have pain in the region where there was complete anesthesia, she said, "Well, that's just it, this numbness is as bad as the pain!" I leave it to the Society to decide the value of her statement.

The third case (in a woman of 32) was not benefited at all. I was so doubtful about the differential diagnosis of hysteria and tic douloureux that I asked Dr. Jacoby in consultation to decide it for me. He thought she had both. I kept her for two weeks in the hospital, but never was a paroxysm observed either by me or any of the assistants or nurses. Being questioned, when she had pain, she answered, with a serene smile, "I have the most excruciating pain now." I have never seen such self-control, and accept her statement. She was not benefited.

These are the three failures. Of four further patients I have been unable to get any report, either directly or through their physicians. When they were discharged, they were free of pain, and grateful. I instructed them to report as soon as the pain recurred, but have not heard from them. One patient, a dispensary case, stayed away after the second injection into the II. branch, and I have not heard from him since.

All the other patients are entirely free from paroxysms and pain. The question now comes up, for how long? So far, no treatment or operation has been able to prevent recurrency of the pain. If, after a resection of a branch the tic returned, the nerve could be re-resected, although this is rather difficult, or the Gasserian ganglion had to be extirpated. But that even this operation does not prevent recurrency with certainty, is shown, aside from other proof in the literature, by the fact that I treated within nine months four cases of gasserectomy with recurrency of neuralgia.

I think it should prove of some interest to shortly describe those four cases where gasserectomy had been performed before.

The first case, 74 years of age, had had six previous peripheral operations performed, and finally gasserectomy. The pain returned in the II. branch fifteen months after operation. When I saw him, he had about twenty attacks a day, sometimes fifty, and a slight facial cramp. After the second injection into the foramen ovale, he was free of paroxysms and pain, and of his facial cramp; a third injection was given prophylactically. Since then, March, 1907, he has been entirely free. I presented him only ten days ago before the Clinical Society of the German Hospital.

The second case, 77 years of age, had a resection of the II. and III. branch and finally gasserectomy. Nine months afterwards the pain had returned. After two injections in the foramen ovale the man was free of pain and has remained so since May.

The third case, a man of 52, had been primarily gasserectomied with recurrence of pain after one year. The man left against my advice after one injection into the foramen ovale in April, 1907, because he considered himself cured. When I saw him in October, he was free of paroxysms, but complained of some occasional slight pain, but not enough to interfere with his enjoyment of life or to necessitate any further treatment.

The fourth case, a well-known minister and preacher, had been suffering for twenty years, had the II. and later on, the III. branch resected, and finally the Gasserian ganglion removed ten years ago. Seven months after the extirpation, recurrency. After a number of peripheral injections in April, with no decided result, I made two injections in the foramen ovale with the effect that three weeks afterwards he was free of pain, but his general condition is now very bad, owing to his excessive use of cocaine.

In a certain percentage of neuralgia cases treated with alcohol injections, recurrencies are said to be expected after eight to fourteen months. So far I have seen none personally, but I have been informed that a patient referred to me by Dr. Collins, whom I began to treat in the I., II. and III. branch and occipital nerve in December, 1906, and who was free of pain according to her statement in May, had by the middle of September a recurrency of the pain. In one of my earliest cases, a colleague, I made one prophylactic injection into the II. branch two weeks ago, that is, eleven months after the beginning of the original treatment. This was done because the patient intended to leave for California for three months, and he had a premonition, as he expressed it, that the pain might return. Besides, he had a certain tenderness near the nasolabial fold. One injection seemed to suffice.

If it is true that all treatmnets and operations, when tested long enough, will not prevent recurrency of the pain, this is very unfortunate, not only for the patients but also for the surgeon, as he is at a loss what further to do. I therefore consider that treatment the most efficient which permits repetition when recurrencies appear. This desideratum is supplied by the injection method.

I have given you to-night my personal experiences as impartially as possible. If asked for conclusions, I would say the following: I consider myself entitled to pass judgment upon the treatment of trigeminus neuralgia, as probably few people have seen fifty-five cases within sixteen months. Of these fifty-five cases I call three "failures," as described above; one patient has had a recurrence, and is out of my reach as she lives in Paris. The rest are free from pain, so far as I know. Of forty-seven I am positively sure.

Anybody who knows how frightfully those patients suffer, must admit that such a treatment, comparatively simple and in the hands of an experienced operator safe, with practically no risk, is a boon to mankind.

116 East Fifty-seventh Street.

INSTRUCTION IN HYDROTHERAPY.*

By SIMON BARUCH, M.D.,

NEW YORK.

To address a representative body of the rising generation of teachers on medicine is a privilege which I value highly, because it affords an opportunity for propaganda in a cause that is near to my heart. It lacks but eighteen months to complete a half century since I entered the medical profession. During the first and larger portion of this period I was unacquainted with the remedial properties of water; during the latter two decades I have endeavored to study and utilize them. A clinical control experiment was thus presented, the result of which I would fain impress on you could I adequately voice the comfort, satisfaction, and the saving of sorrow and suffering which the addition of water to my other therapeutic resources has brought.

*Read by invitation before the Interurban Club.

The development of hydrotherapy during the past twenty-five years has been so phenomenal that it has become imperative to formulate some method of instruction on this subject in our medical schools. The sooner this fact is realized the better for the schools and for suffering humanity. Permit me to illustrate this proposition by a practical example.

The Bath in Typhoid Fever.—You are familiar with the rise of the methodical system of bathing typhoid fever cases, known as the Brand bath. It was originated by a practitioner of Stettin during the Franco-Prussian war and was adopted by the army surgeon with such success that in 1882 the chief of the Statistical Bureau in Berlin, Professor Guttstadt, stated that "the mortality of typhoid fever had been greatly reduced by improved treatment, chiefly the method of Brand." And in 1883 the surgeon-general of the Prussian Army issued a circular in which it was urged that "inasmuch as the Brand bath had saved many lives, it was advisable to utilize this method more frequently in order to save a still larger number of the sick." Despite this testimony from unbiased and authentic sources, this bath never became popular in the civil hospitals and fell into desuetude. What was the cause? The German professor, who is an autocrat in his own school and hospital, treated the Brand bath with indifference and neglected to teach it. Each professor had his own method of bathing typhoids and seemed unwilling to accept the teaching of a private and obscure practitioner. Read the discussions of the Congress at Wiesbaden in 1885 and other societies, and you find that Liebermeistev, Ziemmssen, Nothnagel, Leyden, Fihlene, Naunyn, Immerman, Hagenbach von Mering, Senator, Fraenkel, Strümpell, each speaks ex cathedra of his own temperature, duration, technique, and indications, but not one admitted having subjected the strict Brand bath to a fair trial. Even those who had been converted to the true principle of Brand which was opposed to the antithermic action of the cold bath and advocated its refreshing and invigorating effects upon the nervous system and heart not only failed to credit Brand, but misrepresented him. Witness Curshman's statement in Nothnagel's cyclopedia. "At first," writes the celebrated Leipzig teacher, "under the profound influence of Brand and his successors and in consequence of overestimation of the significance of febrile elevation of temperature, cold baths were given at temperatures as low as 6° to 10.6° (44° to 50° F.), etc." The deplorable result of this indifference to and ignorance of Brand's method, which as you know was quite *the reverse* of that criticised by the professor (Brand never advised a bath below 65° F. and averaged 70° F.) was that its life-saving properties are not now appreciated in Germany, the place of its nativity. When I made the latter statement in the historical section of the Carlsbad Congress in 1902, it was disputed by a Dresden doctor, who said that all typhoids are treated with cold baths in the Dresden hospitals. This colleague had disregarded the fact, as many do to-day, that while every Brand bath is a cold bath, not every cold bath is a Brand bath. Two days later I had occasion to witness baths for typhoid in two of the latest and best equipped hospitals of Germany. One of the physicians had met my question if the Brand baths were used in his hospital by willingness to demonstrate that much milder baths "would reduce the temperature quite as well." When I pointed out after the completion of the bath that though the axillary temperature had been reduced two degrees, the rectal temperature was unchanged, the courteous house physician exclaimed: "Jetzt versteh' ich es."

Here you have one illustration of the dire result of lack of instruction on hydrotherapy.

Now, let me offer you an illustration of the result of correct teaching on the same subject to demonstrate how instruction may save many lives.

In February, 1889, I made an earnest plea for the Brand bath before the New York State Medical Society. The paper was discussed by two colleagues who condemned it. An editorial in the MEDICAL RECORD held that it "is improbable that heroic treatment would be accepted." These discouragements were offset by a request from Dr. Austin Flint, in charge of a division of Bellevue Hospital, in 1889, to explain the technique of the Brand bath to his staff. And it was at once adopted by him and brilliantly continued by Peabody and Ball, who taught it in their clinics and lectures. In 1890 I read a paper in the New York Academy of Medicine, a synopsis of which was published in the MEDICAL RECORD. The report of the discussion states that "Dr. Alfred Loomis said he would take the first opportunity of giving this method a trial," and "Dr. Delafield said that he had no real experience with the Brand bath." Both of these teachers began to teach this method at once, as I learned from reliable members of their classes. That their teaching had fallen on fruitful soil is evident from the fact that in 1902 Dr. Gilman Thompson's textbook on practice stated that the mortality from typhoid fever in the New York and Presbyterian Hospitals had been reduced from 16 per cent. to 6 per cent. by the Brand bath. And in 1903 Dr. H. P. Loomis reported to the Practitioners' Society that "the mortality from typhoid fever in the New York hospitals had been reduced 50 per cent. by the systematic use of the Brand bath." (MEDICAL RECORD, January 10, 1903.)

In 1886 the mortality due to typhoid fever from 1878 to 1886 in the New York hospitals was calculated by Dr. Delafield to be in 1,300 cases 24.66 per cent.; it is evident that the Brand bath had saved about one thousand lives in the hospitals of New York alone during the past fifteen years. Since the method can be more perfect only in private practice, when patients are subjected to treatment in the first week, the total saving of life would seem enormous. *That this was the result of instruction in hydrotherapy* of typhoid fever "goes without saying."

It is your mission to teach your students to save life; hence it is incumbent upon you to add hydrotherapy to the remedial armament with which you equip them for the battle with disease and death.

The attitude of the medical profession of the two countries towards the teaching and practice of hydrotherapy in chronic diseases is quite the reverse of that just depicted, for while it has been taught in Germany for more than a decade, Columbia University is the first to inaugurate a special course by a special chair of hydrotherapy. It may serve to incite you to a desire to emulate this example, to acquaint you with the reason for the sudden and phenomenal rise of chairs and clinics on hydrotherapy in Germany. For many decades Winternitz stood alone in Europe valiantly battling for instruction in hydrotherapy. True, Erb, Charcot, and Semmola practised and advocated it in their respective countries; they did not teach the technique, for the simple reason that *they* had not been taught this most important subject. They sent their

patients to specialists in hydrotherapy. The latter continued to exist precariously in a commercial sort of manner; it was aptly named by Winternitz "the stepchild of medicine." Suddenly there came a great revulsion, and—tell it not in Gath—the reason thereof was the *rise of the Naturärzte*, of whom Father Kneipp was the most prominent exponent. When I visited Germany in 1890 I discovered great alarm, because of the enormous inroads made by these empirics upon the income and status of the medical profession. Witness the plea of Professor Credé (*Berliner klinische Wochenschrift*, 26, 1895) insisting upon the necessity of applying hydrotherapy and other physical remedies in the hospitals, and pleading for instruction in these branches in the universities. He claims with clear discernment that *"if physicians were better versed in these branches, the field of operation of many quacks would be greatly curtailed."*

The serious inroads of these empirics upon the interests of the medical profession led to the appointment of a "commission for the revision of medical examinations," of which that eminent and practical teacher, Prof. Kussmaul, acted as chairman. His report (*Deutsche medizinische Wochenschrift* for 1896) clearly sets forth the alarming conditions which were existing and becoming more acute constantly, and suggests the remedy as follows: "It cannot be denied that the faith in prescriptions is waning among educated people, and that confidence in dietetic remedial methods and in the curative power of water is in the ascendant."

"Even the lower strata begin to realize how much may be accomplished with air, water, and proper regulation of habits of life without the use of medicine. A distrust against even the most powerful and indispensable medicinal agents is becoming more pronounced in large circles. Water is the chief agent, which has won steadily growing confidence as a remedy, because, unlike every other, it may be utilized in varied and changing temperatures and forms of application, for the most varied therapeutic purposes. According to the correct and skilful selection of the procedure, it regulates the circulation and distribution of blood, the production of heat and tissue change, and influences the respiration and the nerves.

"The treatment by water has passed its childhood days when it still staggered upon feeble limbs, and not infrequently did as much damage as is done by improper medication. Ripened experience and physiological knowledge have fortified the treatment and rendered it safe. Hydrotherapy, combined with diet, may undoubtedly bring about, or aid, in the cure of numberless acute and chronic diseases.

"Of hydrotherapy the young physician knows almost nothing when he leaves the university. Unfortunately he sooner or later may encounter discomfiture when an uneducated water doctor steps in and cures the patient after he has failed. Deeply chagrined and disappointed in his confidence in scientific therapeutics, he may pass into the camp of crude empiricism.

"Here lies a great gap in the education of our physicians; here lies the real cause of weakness in the contest for the favor of the public which sooner or later must be encountered by the physician with the layman who may have gotten experience in water treatment or be naturally adapted for it. A revision of our course of study must be made, above all things.

"The teacher of clinical medicine has now so many duties to perform in his work of instruction that no time is at his disposal for familiarizing his students with hydrotherapy. In order to instruct them more than superficially, distinct chairs and clinical divisions are required, in which appropriate cases may be treated by hydrotherapeutic procedures. These lectures could be combined with others on balneology and purely dietetic treatment, but, for Heaven's sake, let not this professorship be connected with that on pharmacology!" (*Deutsche medizinische Wochenschrift*, 1896.)

For the benefit of my colleagues, I wrote in the Medical Record, December 20, 1902 (Observations on German Therapeutics). "This energetic report appears to have borne good fruit. In Jena, Professor Matthes is appointed to teach hydrotherapy in connection with clinical medicine; in Leipzig, Professor Windscheid; in Halle, Professor H. Winternitz (not the Viennese Nestor). In Berlin Professor Brieger was given charge of the new Institute for Hydrotherapy, which he teaches practically and ably, assisted by Drs. Krebs, Lacquer, and Machant. At present clinical lectures are delivered with demonstrations on four days each week, 11 to 12 A.M." (Prof. Curschman, in Leipzig, showed me with much satisfaction his institute for physical therapeutics, and dwelt upon the value of the Wellenbad (wave bath) for increasing bremoglobin and blood cells in chlorosis and anemia.)

"I found quite a number of German, Austrian, Russian, Japanese, and Swiss students in attendance in the large pavilion (constructed for this purpose in the Charité grounds), in which there is an anteroom for polyclinic patients, dressing rooms, and a large room for douches, tub, and other baths. In this room Professor Brieger lectures on practical hydrotherapy. In another building Zabludowski teaches massage. Brieger also has another pavilion of thirty beds devoted to clinic (ward) patients, in which physical methods are chiefly applied. In the near future the outfit for hydrotherapy is to be greatly enlarged. The appointment of this man of exact science to teach hydrotherapy is fortunate for the development of this special branch of therapeutics. Any one who knows the career of Brieger must feel assured that its merits and failings will be cautiously and methodically studied and taught." Brieger was assistant to Frerichs, Onineke, and Koch, and has earned the pseudonym "Pfeilgift Brieger" by reason of his splendid investigations on the Avron poison of the Africans, at the instance of the Imperial Government. From correspondence with Brieger, it appears that the university has greatly enlarged his hydrotherapeutic institute "because of the increased number of students and patients."

In a letter received from Prof. Brieger yesterday, he writes: "I rejoice that hydrotherapy is, under your guidance, gaining ground in America and that it may soon become the common property of physicians as it is with us."

Not alone do most medical schools on the continent teach hydrotherapy, but the interest of this subject has awakened a literary activity in the special lines of physical therapeutics of which hydrotherapy is the chief. A number of special journals are now published, of which *die Zeitschrift fuer physikalische und diätatische Therapie*, by Leyden and Goldscheider, is the most prominent.

Thus has it come about that the "instinct of self-preservation," that most potent of all factors in life, has accomplished what Winternitz and a few earnest

and courageous men had failed to do. May I not urge upon you to draw a lesson from this brief historical résumé?

Happily Columbia University has taken the initiative in this movement for the betterment of our therapeutics. It is surely the most eloquent evidence of my estimate of the enormous import of the addition of hydrotherapy and its legitimate branches of physical therapy that at a time when I lack but a few years of my allotted three score years and ten I am devoting all my energies to the diffusion of knowledge on this neglected and yet momentous subject in the hope of training some younger men to perpetuate my work.

In response to a request I offer you the following outline of the course I have mapped out: Let me say here that ten years ago the late Professor Gaillard Thomas, a man who at all times had the interest of his profession at heart, suggested to the Dean of the College of Physicians and Surgeons the establishment of a chair and clinic on hydrotherapy, with the result that this course was regretfully regarded as impossible on account of the already too crowded curriculum. The elimination of non-essentials by the present faculty appears to have secured the necessary time for teaching this important subject. The senior class is divided into sections of ten or more who receive clinical instruction in the hydrotherapeutic department of the Vanderbilt Clinic on Mondays and Fridays. The first half of the clinic is devoted to demonstration of cases, the diagnosis is briefly dwelt upon, and the pathology and etiology are referred to with a view to point out the therapeutic indications. The aid of hydriatric measures and the reason for their employment, with or without drugs, in the concrete case are clearly gone into and the patient is treated in the presence of the students, who are encouraged to ask explanations of any obscure points. The latter half of the clinic is devoted to demonstration of the technique of hydriatric procedures and students are requested to practise them just as they are taught bandaging or other manual procedures in other clinics. The clinic is under the charge of a chief and two assistants and an attendant, who treats cases under their direction on Mondays, Wednesdays, and Fridays from one to four P.M. Only males are treated for obvious reasons. Female patients and cases not required for teaching are referred to the Riverside Association, Hydriatric Department, which is under my direction, and treats about fifty cases daily. Wednesday afternoon is devoted to experiments in hydrotherapy. A course of lectures during the latter half of the semester is also provided for in which I propose to dwell upon the principles of hydrotherapy and their practical application in disease. The final examination will contain not less than two questions on hydrotherapy.

Before concluding you shall witness a demonstration of our successful treatment of sciatica, which so often eludes medicinal and other measures. [The Steam Scotch Douch was demonstrated on a patient. The douche table was also demonstrated to show the importance and feasibility of exact "dosage" by changing the pressures of duration and temperatures.]

In conclusion let me admonish you to ponder upon the facts and deductions presented in this brief time, and to indulge in the hope that you may become imbued with the desire to arm your students with this additional potent weapon against disease and death.

135 West Seventy-third Street.

THE TREATMENT OF CHOREA MINOR, WITH ESPECIAL REFERENCE TO THE DANGERS OF THE ARSENIC THERAPY.

By HENRY KOPLIK, M.D.

NEW YORK

If one were to step into the consulting rooms of the practitioner to-day he would find that to a child with chorea minor the first drug prescribed in most all the cases would be Fowler's solution, and the first injunction to the parents of a patient suffering with chorea is to put the little unfortunate to bed. If the practitioner wished to be thorough, he would probably advise that the room be darkened, and utmost quiet in the surroundings of the little patient should be the keynote of management. So common is it to find this the therapy of the general practitioner, and so universal is the support he will get from the text-books, either special or general, for his procedure that the conclusion is forced upon us that chorea minor, as far as its treatment is concerned, has not received that attention of late years accorded to more innocent affections of early and late childhood.

If the progress of our knowledge of the etiology of chorea is still slow, there are some facts which it will be well to consider as universally recognized. The disease partakes in its course and manifestations the character of an acute infectious disease of self-limited duration. In a certain number of cases there develops from the outset a cardiac lesion, an endocarditis. In another set of cases this cardiac involvement may not be evident in the first attack, but will appear in some subsequent recurrence of the disease. In other cases we have the chorea as a sequel or accompanying a so-called articular rheumatic attack. That chorea minor therefore is an infection pure and simple, and that in some cases this infection is apt to attack the cardiac structures can no longer be a matter of doubt. In the face of this it is all the more surprising that the therapy of chorea minor has of late years not been in keeping with the above recognized facts. The therapy of chorea minor must sharply differentiate between the various sets of cases and their degree of severity. It is hopelessly incorrect to apply the same therapy in all cases, and it is no doubt productive of considerable harm to do so. It is certainly improper to apply the same methods to a case of chorea complicated with even slight endocarditis as to a case in which the heart is still free from involvement. It is likewise too severe a procedure to cause a case of slight, mild manifestations to undergo the same segregation we would apply to a severe paralytic chorea. There are certain cases in which arsenic acts as a direct poison, and others in which this drug is comparatively well borne, and it is the purpose of this paper to emphasize that the indiscriminate prescription of arsenic is even more harmful than the prescribing of quinine in every febrile case. Arsenic is more dangerous because its effects in a certain direction, strange to say, have entirely escaped notice. I refer to the kidneys. The toxic effects of arsenic have been known for some time through the writings of Osler, Lees, Martin, Marshall, and a number of writers, too many to note here. One of the most recent cases is that of Lees in which arsenical neuritis resulted from the administration of M XV of Fowler's solution for five weeks with resulting paralysis of the tibial muscles, and extensors of both wrists as well as pigmentation of the skin. In a report recently given

to me personally the number of cases of neuritis as presumed to follow the administration of arsenic in a certain hospital were so frequent as to cause a suspension of the administration of the drug.

I will not stop longer than to mention a few other symptoms, such as vomiting, edema of the eyelids, skin eruptions, with the above forms of neuritis as manifestations even under moderate dosage of the toxic effects of the drug. My own hospital service includes a large number of the various forms of chorea minor, both those complicated with or complicating endocarditis, the very mild forms, and those which are so severe as to be placed in a separate category of paralytic cases. In these cases the patients are unable to walk or use the extremities, and in some instances unable to lift the arms or lower extremities. In the severest forms of paralytic chorea the organs of speech are affected, the patients cannot phonate, and are mentally much depressed.

I have thus been enabled to form a definite picture of the disease in all of its manifestations at the bedside, and to formulate the methods of therapy along lines consonant with our knowledge of the disease. It has been my custom in all cases of chorea to watch the action of the kidneys, more especially in cases which are receiving the arsenic therapy. My method has been to begin with one drop three times daily of Fowler's solution and to increase *one drop* a day (not three times daily) until a point has been reached which is called tolerance, that is, until there is a slight puffiness of the eyelids. As a rule, with older children ten drops three times daily is a maximum dose. A close study of the urine revealed a most interesting phenomenon. In some cases before any stomach uneasiness or puffiness of the eyelids were apparent a slight trace of albumin appeared in the urine. If the administration of the drug was continued casts would appear, and in some cases blood cells. At first the cases were regarded as exceptional. In none of them was there any cardiac lesion, and in all the cases the urine not only was free from renal elements on admission, but cleared up on suspension of the arsenic. It soon became evident that these cases were not exceptional, but formed a marked proportion of the cases of chorea which were receiving arsenic. In some cases the dosage was quite small, five drops three times daily to a child six to eight years of age, the drug was suspended in some cases and, as the urine cleared, the administration cautiously begun until it was found in a few days that the kidneys again reacted and then the drug was permanently suspended.

Another interesting feature was recently brought to our notice. Albumin and casts appeared in a number of cases in which the administration had been kept within bounds of moderate dosage. It was suspected that the preparation of Fowler's solution might be unstable, and indeed analysis showed our Fowler at that time to have evaporated to an extent as to make it fully twenty-five per cent. stronger than the officinal preparation. Thus unless freshly prepared Fowler's solution gathers strength. Although this was the case with a recent preparation, the dosage allowing for the increase of strength only exceptionally ran beyond ten to twelve drops three times daily. We have proven then to our satisfaction that in a definite number of cases Fowler's solution is an irritant to the kidney, causing the excretion first of a trace of albumin, which in time becomes more marked, and is then accompanied by casts and blood cells. In view of the above, long before a puffiness or edema of the eyelids occurs, we have in a study of the urine a most delicate test of the point of tolerance for arsenic. That is, when a trace of albumin occurs in the urine it is time to stop the drug no matter how small the dose or how excellent the general condition as to the other signs, such as the absence of puffiness about the eyes or gastralgia. So convinced am I of the delicacy of this test that I now administer arsenic with a daily examination of urine, except in cases in which the dosage of arsenic is exceedingly small, approximating what is for the sake of a better term called tonic dose.

Of the recognized treatment of chorea not much can be said in praise and quite some in criticism. The total disregard of child nature which causes the complete isolation of a child in a dark room for an indefinite period seems well nigh brutal, yet this is what is done, and what I find of daily occurrence. Children need air and sunshine in health and disease—to deny it to them on the ground that by thus doing we quiet the nervous system seems to me hardly a tenable proposition. In fact most children are made much worse for fretting and worry if put in what is practically solitary confinement. Again to give a drug such as arsenic to a point of tolerance, disregarding the ill-effects of the drug on the general well being, the appetite, the stomach, the nervous system, the kidney without even the supporting conviction of a specific effect seems to me intolerable. Yet I find this is daily practice simply because it has been recommended from authority to authority. No one seems to have had the courage to look into the action of such a powerful drug on the disease or on the economy of the child.

What, then, will be the basis of a rational treatment of chorea minor. In the first place it should be granted that the disease is a self-limited one and the most we can do is to endeavor to protect the patient against anything, such as undue excitement or exposure, which might exacerbate symptoms. We know that a mild form of chorea may pass rapidly into a severe form of chorea insaniens under the influence of undue nervous strain or excitement. We should place the patient under the best hygienic management and should remember that drugs at the most only aid us to attain the above ends.

The mildest cases of chorea minor in which there are twitchings to a limited degree, and in which the patient is able to be up and about, are best managed by a modified rest cure. The patient retires to bed early and arises late in the day (10 A.M.). Before rising a light breakfast is taken in bed. Before breakfast the patient is given a warm bath and a cold water rub down, is put to bed, and after an interval of an hour partakes of the above light breakfast. The patient is then rested and at 10 A.M. arises and is indulged in the ordinary duties of childhood. At midday, after luncheon, the patients are encouraged to rest whether they sleep or not for an hour, and they may again indulge in mild play or read. Early in the evening the patients are put abed (5 P.M.) and at 6 P.M. a light supper is partaken of, and after an hour of reading or occupation in bed the little ones are encouraged to sleep.

This is the main regimen for mild cases without any cardiac involvement. It is unwise to give such cases increasing doses of Fowler's solution. They certainly are not benefited by it. More to the purpose is the constant administration of a sedative, and one which can be utilized with considerable

effect is sulphomethylmethane (trional), 5 grains three times daily, or chlorotone in very small doses, the final dose being given just before retiring. Light nutritious food must be chosen, and of these milk and eggs with very little meat should be the mainstay of the diet. If there is sleeplessness to a marked degree a dose of the mixed bromides is quite sufficient. Open air, play without undue excitement are more in accord with child nature in these cases than isolation, darkness, and depressing surroundings. The latter only aggravate the symptoms of the disease.

The moderately severe cases are those in which the chorea is seen to interfere with the mental stability of the patients; they become morose, melancholy, or are subject to outbursts of temper. The choeric movements interfere with coordinate locomotion, objects are dropped, and speech is notably affected. Such cases are put abed, but not completely isolated; they should be surrounded with quiet, but even here a little play is useful therapeutically. It is unnecessary to darken the room except when asleep or inviting sleep. If there is slight or marked cardiac involvement no arsenic should be given; such cases do very badly under arsenic therapy; the appetite is interfered with, and I really believe the cardiac condition is aggravated by the stomach distress and nausea caused by physiological dosage of the drug, not to mention the kidneys. In these cases, if well borne, moderate doses of sodium salicylate are useful for the alkaline effect only and possibly as a prophylactic if there is a rheumatic tendency. If the salicylate of sodium is badly borne, no drug beyond a sedative given in the mild cases should be used, nor should digitalis be given to drive the heart. Of great use in these cases, it has seemed to me, was the administration of strychnia as a bitter tonic. In fact, in some cases it is the only drug we should turn to.

The hygienic management of the mild cases is continued in these cases. If arsenic be given it should be only in cases free from cardiac involvement. Inasmuch as some will insist on the use of arsenic, it should be given with frequent examination of the urine in order to detect any sign of deleterious action of the drug, as above indicated. As I have repeatedly said, arsenic in my hands has never cut short nor modified the course of chorea minor, and if I do turn to it it is only to use it in small doses. The use of arsenic in ambulatory cases is to be deprecated.

Of great utility in cases of the second class is hydrotherapy. Children take kindly to this form of hygienic and toning treatment. In the morning, an hour after the early breakfast (glass of milk and crackers), the little patients are given a pack at 100° F., and the temperature of this pack is gradually lowered by the addition of cold water on the pack, the patient, pack and all, is wrapped in a warm blanket for fifteen minutes, and then the blanket removed, also the pack, and a good rubdown, with cool water, given to secure reaction. A child's skin should glow after such procedure, and complete rest is enjoined until the second and full breakfast, which may be given an hour after the completion of the pack treatment. A little quiet play is useful in bed cases, but if play is accompanied by undue excitement, it must be restricted. Visitors in my wards are astonished that choreas are not confined in darkened rooms. Why should they be? . . . it aggravates the disease. Children who are sitting up in bed like to see and talk to other children; to deny them this is a hardship and not in accordance with their natures. They do better for the agreeable quiet companionship of other children. The diet in these cases, as in those of the first class, should be light and assimilable, meat and vegetables in moderate quantities being allowed.

The severest forms of chorea minor are those in which speech is lost. The children are mentally depressed, there is absolute loss of coordinate motion, there is a constant motion choreic of all the body, and in severest forms there is a paresis in which the extremities either cannot be moved at all or but to a limited extent; any attempt to move them only calls forth choreic movements of the face, tongue, and trunk. Some of these cases can neither raise nor lower the extremities. When any approach is made the patient becomes very uneasy; either cries or becomes extremely restless. Such cases cannot support the body weight, they are for the nonce paralytic, and are indeed called paralytic chorea. In most of the cases of this class there is no endocarditis, though the heart action may be extremely weak. In these cases I think the use of arsenic is fraught with danger, for, though we have means of judging the limits to which the drug may be pushed, we may go a little too far and add a neuritis to our already helpless picture. In these cases more complete isolation is indicated than in cases of the previous class, no communication should be allowed with other children, and yet there should be sunshine and air. Inasmuch as some of these cases at first or in course of the disease are thrashing about in bed and are apt to injure themselves, the sides of the bed should be padded and the knees and elbows bandaged so as to avoid abrasions, which otherwise would occur. In girls the hair should be neatly done up in a species of cap to avoid matting. Here the sedative treatment, hydrotherapy and strychnia, lend their best aid to the physician. These cases, which I may in a future communication dilate upon more fully, are very trying to the physician and nurse, and only patient waiting, careful diet, and nursing are eventually rewarded with success. In these cases, after the choreic symptoms quiet down and mentally the patients are depressed, much benefit is attained both mentally and otherwise by getting the patients out of bed in an invalid chair, in a sunny room, and with the intercourse of quiet children.

I have in this paper not touched upon those cases of chorea minor affected with endocarditis, or those rheumatic cases, so-called, which are complicated with chorea, because I wished to point out clearly the treatment pursued successfully in uncomplicated chorea minor and to demonstrate as fully as I could the dangers of arsenic and the futility of its use in this disease.

692 Madison Avenue.

MEDICAL AND SCIENTIFIC WORK IN NEW YORK STATE CHARITABLE INSTITUTIONS

By ANDREW MACFARLANE, M.D.,

ALBANY, N. Y.

The consideration of the care of the insane in this State, involving as it does the welfare of 28,000 of the most sadly afflicted of mankind, the expenditure of $6,000,000 annually and provision for constantly increasing numbers is a subject which should appeal to the economist, the philanthropist, and the scientist. The evolution of the management of the insane

*Read at the New York State Conference of Charities and Correction, November 13, 1907.

has been from the county houses to State custodial oversight, as at Willard and Binghamton, then to scientific medical care. The ultimate goal of medical and scientific work must be the better understanding of mental abnormalities with the diminution of insanity by the prevention of the passage of the acute, curable forms of insanity into the chronic incurable types.

The removal of the insane from the county houses by the State Care Act in 1890 to the direct control of the State placed the responsibility for the well-being of these unfortunates upon the people of the State, and this real white man's burden must continue for all time.

The first effect of this humanitarian impulse was to crowd all the State Hospitals with a mass of patients for whom little medically could be done, thus essentially interfering with proper classification. Gradually the needs of the acute, curable insane were recognized. Schools for more efficient nursing were established, infirmary wards instituted, laboratories developed, more scientific case records evolved, and medical conferences frequently held.

In spite, however, of these great advances during this time, the medical care of the insane in State Hospitals has not progressed with the same strides as have the other branches of medical science. The reason for this is partly inherent to the work itself and in part the result of conditions which might be remedied.

The superintendents of these enormous institutions with two thousand patients or more are no longer able to devote themselves to the strictly medical care of their patients. Their time is necessarily taken up with the consideration of the general affairs of the institution rather than the direct medical care of the individual patient. As a result there is a tendency for the entire staff to lack that inspiration and impetus to clinical medical work which only the head of an institution is able to give. Then too physicians in State work lose the stimulation of competition and outside rivalry which develops the best in a man. They too often also miss the joy of their work and the ennoblement which comes from seeking to advance human knowledge no matter what the subject may be.

Physicians in the outside world who do not take part in the scientific discussions of their societies, who do not seek to broaden their knowledge by occasional post-graduate work, who do not aim to become progressive by attaching themselves to some general hospital, drift along, are distanced in the daily struggle, and at fifty are practically in the same scientific position as they were at thirty. Human nature is the same in State Hospitals except that promotions there are too often made on account of duration of service rather than medical efficiency. It would seem as if there might be a method devised without doing injustice to anyone whereby the drudges, the drones, and the commonplace should not altogether stand in the way of the alert, the progressive, and the efficient. The good of the whole service should be kept in mind and not entirely the welfare of the individual.

It is a fair assumption that at least nine-tenths of the patients in State Hospitals are the chronic insane. The care and management of this greatly preponderating majority must give its impress to the entire institution. The variety of occupations, the care of the farm, the question of buildings, the forms of amusement become of much more seeming importance or at least urgency than the examination of the blood or spinal fluid, the determination of changes in metabolism, the careful analysis of statistics, the keen observation of psychological processes, and the scientific correlation of clinical symptoms at the bedside with pathological findings at the post mortem.

In spite of the fact that the State is ever planning and building new institutions, the number of the insane in the State is increasing more rapidly than the accommodations. The inevitable result everywhere is overcrowding with unsatisfactory classification and loss of medical efficiency. The public, the medical profession, and the State officials must grasp the fact that the care of the insane in New York State is to-day the biggest kind of a problem and that it is a medical problem. True economy consists not in petty cheese-paring, but in a breadth of view which seeks the greatest good for the largest possible number. The solution of this problem lies either in a general hospital for the acute insane, in the hospitalizing of the old asylums, or part of it, or in both.

The State has recognized both these remedies and has or is constructing reception pavilions for the acute, curable insane in connection with the State Hospitals at Buffalo, Rochester, Utica, Middletown, and Poughkeepsie and has also appropriated $300,000 for the construction of a psychopathic hospital in New York City.

The effect of both of these tendencies is to separate and isolate the insane from the sick people and to unconsciously maintain the idea that the insane are different from other sick people and have no connection with general medicine.

Germany, which has taken the lead in modern clinical medicine, is also in the van in the science of psychiatry. The great names in Germany are not those in charge of large institutions, but the directors of small psychiatric clinics connected with a university general hospital. Kraepelin at Munich, Wernicke at Breslau, Krafft-Ebing at Vienna, Zieben at Jena, occur to the mind at once as the leaders in the science of insanity. They have each a small number of acute cases, who can be closely observed, thoroughly studied, and scrutinously examined in every detail. The resources of a great university—clinical, experimental, pathological, are at their command. Would anyone for a moment doubt that the care of the insane under these conditions was not a purely and strictly medical question? Germany with its nineteen famous universities has nineteen psychiatric clinics to which the acute insane are sent from their respective districts. How can New York State meet this sysyphean problem?

If the superintendents are unable to give time to the individual cases, then the first assistant physician's position should be elevated and he should be held responsible for the medical work accomplished. Just as in one of our huge modern vessels there is a captain, the executive officer, and a chief engineer who is responsible for the working of the vessel, so in these enormous institutions the superintendent could confine himself to the executive work and the chief medical officer to the direct medical oversight of the patients. Such an arrangement would provide honor enough for both. The other assistants would be stimulated to special research and as a result of their work, could be placed in charge of their reception pavilions and would be in line for chief medical officers.

Although National and State service by its routine is often destructive of original work, still there are enough exceptions to prove that it is not impos-

sible. I need only mention the British army surgeon, Donald Ross, who worked on the problem of malaria in India when the perspiration from his head rusted the microscope he was using, the fatal dangers to which our army surgeons, Drs. Reed, Lazear, and Carroll gladly subjected themselves in solving the problem of yellow fever. There is no reason why under proper stimulus the same results should not be shown in our State Hospitals.

There are two forces in nature affecting every organ and every human creation. Their harmony makes the perfection of the universe and the wellbeing of every organism. They are the centrifugal and centripetal forces. It is the same question, old as the race, even the universe, centralization and decentralization.

The care of the insane was at first local, then it became centralized and the question now arises whether it may not with profit be decentralized to at least a slight but important extent.

The cry for the human when ill is for home and it takes no stretch of the imagination to picture the agony of one of these poor creatures taken from home to a distant city and placed in a huge structure with strange surroundings. The State has appreciated this need and has appropriated the ridiculous sum of $300,000 for a psychopathic hospital in New York City, while Munich with one-quarter the population and probably less than one-tenth the wealth has spent over $500,000. A similar sum would easily construct a psychopathic pavilion in connection with general hospitals in at least ten of the cities of this State. To these psychopathic pavilions every insane patient from that section could be sent. If after a few days' observation the patient was seen to require State Hospital care, he could be regularly committed to such a hospital. If it were determined that a stay of a few weeks would probably be sufficient to induce recovery, then no commitment would be necessary and the patient would escape the stigma of ever having been officially declared insane.

The ownership of these pavilions would remain with the State which would necessarily exercise some control over its general management. Such detention pavilions under local control have been in operation in Bellevue for years, in Albany for four years, and accommodations for the acute insane in general hospitals are being arranged in Auburn and Rochester. The University of Michigan has a pyschopathic pavilion in connection with its university hospital.

The State might easily and successfully train in its State Hospitals men who would accept the superintendency of general hospitals and the especial charge of the psychiatric clinic. These men after a term of service might be made eligible to superintendencies of State Hospitals. The inevitable result would be that the medical care of the insane would be placed on the highest possible plane.

That State Hospital trained physicians make good executive heads of general hospitals is demonstrated by the successful administrations of Dr. Henry Hurd at the Johns Hopkins Hospital and Dr. Goodwin at our Albany Hospital. The reverse that superintendents of general hospitals may become efficient officers in hospitals for the insane is shown by the brilliant career of Dr. Cowles who went from the management of the Boston City Hospital to the McLean Hospital and has since played a prominent part in American psychiatry.

The growth of knowledge is through the diffusion of knowledge and the marvelous advances of the past half century are due to the fact that workers all over the world know almost instantly the results obtained by their coworkers in every part of the globe.

Our knowledge therefore is nothing more nor less than the collation and deduction from findings or statistics. We know that the sun will rise to-morrow because it always has risen. We know that general paresis and paranoia are chronic, progressive, incurable diseases because they always have been. There are many facts, however, about insanity which are still unknown or at least very hazy, and we need statistics to shed light upon these dark places. What effort is our State with the enormous material in its possession making along this line?

Would not one or two statisticians, devoted to this work, after a time illuminate some of the problems connected with the etiology and prevention of this affliction which might be of incalculable value to the human race?

One word more—It is a well known fact that every successful business house takes an inventory yearly of its business in order to avoid the mistakes of the past and to ascertain exactly their present position. Some progressive firms even employ an outside expert at a large salary to investigate their methods of conducting business and to recommend changes which would be more economical and more efficient. The State could copy these methods of successful business and after seventeen years take stock of her work.

A commission consisting of members directly connected with the State care of the insane, of well known neurologists and general practitioners, of level-headed and broad-minded laymen might with great profit even at considerable expense investigate the present status of the care of the insane, ascertain the best methods of treatment, and provide a definite plan to meet this ever-present and constantly-increasing problem.

No greater blessing could come to the insane and also to the State than to maintain the work of her State Charitable Institutions on a truly medical and thoroughly scientific plane.

198 Washington Avenue.

PREVENTION OF DEATH DURING ANESTHESIA BY CHLOROFORM AND ETHER.*

By ROBERT REYBURN, A.M., M.D.,

WASHINGTON, D. C.

PROFESSOR OF HYGIENE AND PREVENTIVE MEDICINE, AND DEAN OF MEDICAL DEPARTMENT, HOWARD UNIVERSITY, WASHINGTON, D. C.

One of the most horrible occurrences that can happen to a physician is the death of his patient during anesthesia. It is unfortunately true that in a certain indeterminate number of cases, death will occur during anesthesia by these substances, when every precaution has apparently been taken and the anesthetic has been given by trained experts, yet I believe that the number of the fatalities we now meet with is greater than can be properly accounted for, and arises from the neglect of certain precautions, which it is the object of this paper to endeavor to point out.

As yet we have discovered no perfect method of producing anesthesia. What we want is some substance that is capable of producing insensibility to pain without danger to life, and it is to be hoped that in time our chemists may discover it.

*Read before the Medical Society of the District of Columbia, October 23, 1907.

It is the belief of a great number of the members of the medical profession that anesthesia by ether is almost devoid of danger to life. This belief is not shared in by the writer, and in his opinion anesthesia by ether is nearly as dangerous as that by chloroform. It is true, death does not usually result as quickly during ether anesthesia as it does during the administration of chloroform, yet the fatality is just as certain to result, in a number of cases, in the one as in the other.

Death by chloroform is usually speedy and almost instantaneous. The respiratory and cardiac centers are so overwhelmed by the poisonous vapor that the patient sinks quietly into eternal sleep. Death by ether is usually, though not always, differently produced, and occurs in one of two ways.

In the first method of death it may occur in a way very much resembling that of death by chloroform, and there is sometimes asphyxia by the concentrated ether vapor, with speedy death. The writer has seen ether given for anesthesia in a most reprehensible manner. He has seen the ether cone held over the face of the patient so closely as not to allow the proper admixture of air in spite of the struggles of the patient. He objects to every complicated apparatus for the induction of anesthesia, and objects even to the cone, for in a prolonged operation the cone often becomes so wet with the ether as to give a too saturated vapor to the patient. A simple metallic framework covered with one layer of muslin is much better, and the drop method of anesthesia, should always be used, whether chloroform or ether is the agent employed.

One reason for the fatality during anesthesia has been that undergraduates, in many of our hospitals, have been allowed to administer the anesthetic. Anesthesia should be regarded as a major operation, which always involves danger to life, and should always be administered by experts, and under the strict supervision of the surgeon.

Another and slower method of death during ether anesthesia is very different from the first, and may occur at any period, from five days to a month after the period of anesthesia. This is caused by the ether vapor in prolonged anesthesia being absorbed in large quantities, producing a form of acute nephritis, which may cause suppression of the urine, coma, convulsions, and death.

About twenty years ago the great English surgeon, Lawson Tait, wrote an article describing the histories of several cases of deaths, occurring at periods varying from a few days to a month after surgical operations, in which ether had been used as the anesthetic. This condition admits of ready explanation, when we recall that the renal artery is one of the largest branches given off from the abdominal aorta, and hence furnishes a ready vehicle for the absorption of the ether vapor.

Deaths after ether anesthesia may also occur by the irritating effect of the vapor upon the bronchial mucous membrane. When we consider the enormous surface exposed by the terminal bronchi and air-cells to the action of the atmosphere and to any vapor mixed with it, this is not to be wondered at. Dr. Dalton estimated that the air-cells of the lungs exposed a surface of sixteen hundred square feet.

Ether vapor is to many persons excessively irritating and produces a form of bronchitis or bronchopneumonia, which in a few days may prove fatal.

How can the first method of sudden death from either chloroform or ether be averted?

The first step, and one to which I attach more importance than any other, is the rapid inversion of the patient and preferably in the prone position. Late researches on the resuscitation of drowned persons have shown that the prone position for the revival of such patients is much better than the supine, and that artificial respiration in that position is much more effectual.

What is the mechanism of the sudden death in these cases? I believe that it is directly caused by the column of venous blood filling the jugular and innominate veins, thus pressing upon the auricle and preventing it from opening. When the patient is rapidly inverted (with the head downwards) the venous blood drains back toward the brain and allows the auricle to open and the circulation to begin. Of course, this must be done instantly, for seconds, not minutes, count for life or death. I do not believe much in the hypodermic use of strychnine or nitroglycerin in these cases, for before the drug can be absorbed, the patient is usually dead.

The hypodermic use of suprarenalin solution is highly recommended in this class of cases, but I have not had the opportunity to use it. A faradic battery is often of inestimable service and should invariably be at hand when a patient is about being placed under an anesthesia.

I well remember a case of threatened death during the inhalation of a mixture of chloroform, alcohol, and ether (the A. C. E.), which taught me a useful lesson. A woman patient in Freedmen's Hospital required a simple incision, and at first it was not intended to use any anesthetic. The patient, however, objecting, with inexcusable carelessness (without calling for an assistant physician who was in the next room) I reached to the side table and taking the inhaler, poured an ounce or two of the mixture in the cone and caused the patient to inhale it. To my horror the patient, after a few whiffs of the mixture, suddenly collapsed. Her breathing ceased, her heart stopped beating, and she was practically dead.

A man can think a good deal in a few seconds at a time like that. There was no time to call for assistance, so I quickly threw the patient over my shoulder, with her legs in front, and the rest of the body, head downwards, hanging down my back. After two or three minutes, which seemed to me like hours, had been passed in this position, I heard a gasp of returning breathing, which seemed to me the sweetest sound I had ever heard; the patient rallied without any further trouble.

I have seen many narrow escapes from death during anesthesia, but the only case of death I remember that actually occurred while I was present was in the case of Rev. Father Boyle, in Providence Hospital, some years ago. In that case, which was during ether anesthesia, the face of Father Boyle turned perfectly black. In such a condition of venous stasis, I would suggest, if other means fails, the opening of one of the jugular veins to relieve the pressure of the column of venous blood which shuts up the auricle and stops the circulation.

The delayed death which occurs from the poisonous action of the ether vapor upon the kidneys and the bronchial mucous membranes is largely preventable, and is due, I believe, chiefly to the prolonged anesthesia. I would earnestly plead for rapid surgical operations. When an operation is prolonged over one or two hours the danger to the patient is enormously increased, not only from the ether vapor but from the toxins which are accumulated in the system during anesthesia.

I never saw a death occur during anesthesia while on duty as Medical Officer during the Civil War, 1861-5. The anesthetic employed during the Civil War was mostly chloroform, but the A. C. E. mix-

ture was used considerably in the latter stages of that terrible conflict. I had an abundant experience in the induction of anesthesia, both during the Civil War and for many years subsequent to this period.

I reported for duty on May 7, 1862, as Acting Assistant Surgeon, to the Surgeon General's Office, and had expected to be ordered to join the army of General George B. McClellan, who was then waging his disastrous campaign on the peninsula in front of Richmond. Very much to my disgust, however, this order was countermanded, and I was ordered to report to Surgeon John E. Summers, Medical Director of the Hospitals in Alexandria, Va. This change of program was, however, ultimately greatly to my professional advantage. The disastrous campaign of General McClellan in 1862 culminated in the Northern Army being driven back from the vicinity of Richmond, to the region of country in front of and adjoining Alexandria, Va. The Battle of Manassas (or, as it is often called, the Second Battle of Bull Run), the Battles of Cedar Mountain, Chantilly, and the two battles in front of Fredericksburg, were all fought within a short distance of Alexandria.

The rush of wounded and sick soldiers to our hospitals after these battles was almost indescribable. After taking possession of every empty house, church, school-house, and public building in Alexandria for hospital purposes, after the Battle of Manassas, we fed in one day twenty-two hundred sick and wounded soldiers who were still in the ambulances and army wagons in which they had been conveyed to Alexandria, and who could not be housed for lack of accommodation.

There is one fatality that has not been mentioned, which is the result of chloroform anesthesia, and this is acute yellow atrophy of the liver and kidneys. The following extract from the MEDICAL RECORD of October 19, 1907, is illustrative of this point: Guleke's patient was a robust young woman on whom a herniotomy, lasting half an hour, was performed under 25 c.c. of chloroform. The anesthesia was unusually smooth; hernial sac contained only omentum. Jaundice and cholemia developed in less than twenty-four hours, and at the end of ninety-two the patient died in coma after delirium and convulsions. The microscope revealed extreme destruction and fatty degeneration of the cells in the liver and in the convoluted tubules in the kidneys. The chloroform was evidently responsible for the trouble, as infection and thrombosis could be excluded. The same chloroform, used for other patients the same day, caused no by-effects in other cases.

All the similar cases of yellow atrophy of the liver on record, following administration of chloroform terminated fatally in from three to six days. The patients were generally young and robust. It is noticeable that the operations had always been abdominal and that the patients were moderately or extremely fat. Other facts are cited which suggest that an unusually fat liver is less resistant to chloroform than one less so."

Finally, to recapitulate the precautions in giving an anesthetic:

1. Give the ether or chloroform drop by drop.

2. Operate rapidly, thus diminishing the time of anesthesia.

3. Invert the patient, in case of threatened death, preferably in the prone position.

4. Have a faradic battery ready.

5. Use artificial respiration.

WRITER'S CRAMP; WHAT IT IS AND HOW IT CAN BE TREATED BY THE FAMILY PHYSICIAN.

BY S. H. MONELL, M.D.,

NEW YORK.

THIS condition is usually classed with the neuroses and referred to neurologists, but the experience of fourteen years in the study and treatment of cases leads me to the reasonable conclusion that it is a state of chronic fatigue and should be treated as such. My excuse for again presenting this subject is the desire to assist the ordinary practitioner to relieve his own cases, for sufferers are scattered everywhere, there being no fewer than fifty thousand in the United States, most of them working for small salaries and unable to travel far or pay a specialist.

If I recollect rightly the MEDICAL RECORD in the first thirty years of its publication printed but one article on writer's cramp by any physician.

About ten years ago the writer prepared a monograph covering treatment with resources then in use, but it has long been out of print and the introduction of newer apparatus has affected favorably both the prognosis and methods employed. The need of calling attention to present means of affording relief is brought to mind by the following letter which prompts me to add to what I have hitherto written:

Stratford, England,
November 14, 1907.

Dr. S. H. Monell, Dear Sir—Seeing your book, "The Cure of Writer's Cramp" sold by a London firm of publishers, I bought the same, as I am troubled with writer's cramp, both in telegraph keying and writing. It was a disappointment to me to find that it would have to be a case of going to New York for treatment. This is a course which is impossible for me for several reasons: first, financially, second, if I gave up my present position I couldn't obtain another, and also that I depend on my present post for a living. I write to you under the hope that possibly you may know some one either in London or England who is qualified in giving your course of treatment. I am 27 years of age and have been troubled with the cramp for close on six years, till now keying and writing are both absolute torture: in fact nearly a physical impossibility. I have tried everything and anything but it is no good and I am threatened with dismissal for incapacity. I feel depressed and miserable.

Possibly when looking at my writing you might think that my cramp isn't as bad as I make out, but this letter is an hour's effort."

Signed.....

Appeals of this kind are pitiful and sufficiently warrant the space taken in briefly telling the home physician what he can do in ordinary cases.

First, an explanation of the real character of writer's cramp will simplify matters in the minds of many who have puzzled over theories as to whether the "neurosis" was central or local. When a healthy person tires his arm by unusual work for a brief time, the muscles have the power to recover from the lameness and exhaustion by natural rest, especially if aided by a little stimulus to the circulation. But this natural power of recuperation will not stand too much abuse, and has its limitations. If overtax is continued day after day in excess of the elastic capacity of the muscle fibers the nutritive regeneration of the tissues does not keep pace with the

waste of wear, and rest becomes less and less restorative, because incomplete.

In time then in severe cases nature ceases to eliminate the poisons—the toxins of combustion—that result from work, and by remaining in the tissues they irritate and enfeeble the muscle fibers and their nerve supply so that aches, pains, heaviness, stiffness, lessened rapidity of contraction, lack of endurance, nagging irritability, and gradual "loss of grip," cramp, spasm, and palsy, mark the downgrade of the overworked arm and hand.

When the same set of muscles and the same coordinating functions of brain centers work day after day in writing or telegraphing at a rate of speed beyond the normal endurance of the given person, there develops a chronic state of fatigue which finally becomes a localized "disease," inasmuch as the person so affected cannot restore the functions of the impaired muscles to normal by either rest or exercise.

The main indications for treatment are, broadly, two: the elimination of the toxic products which result from high pressure muscular work and part of which gradually stagnate in the tissues, and the improvement of the nutrition of the affected tissues so that the powers of recuperation are renewed.

The first of these indications is admirably met by means of the modern electric light radiant-heat cabinet bath, and if this is not available for the practitioner he should advise a course of Turkish baths as the next substitute. The superiority of the radiant-heat bath over the conducted heat bath is, however, demonstrated by many tests which show that it produces nearly double the amount of perspiration in the same length of time, with an increased elimination by the skin and an important stimulation of vital activity. The living tissues are porous to rays of "radiant heat" while conducted heat penetrates more slowly and with less of the effect desired. This elimination must underlie direct treatment to make it satisfactory. Prior to my demonstrations of this in practice the results secured were rapidly obtained only in commencing cases, while the treatment of the last stage of total disability was tedious and exceedingly difficult.

The measures of direct treatment are comprised in the resources of electrotherapeutics. In employing these resources there are but three requisites to success; a determination of the therapeutic actions which must be set up in the tissues to promote their restoration to normal; the selection of the means of best setting up the desired actions, and the technical knowledge of how to make the selected agent do the therapeutic work that the operator intends it to do.

No special skill, apart from a general command of the resources of modern electrotherapeutics, is therefore required to enable the physician to undertake a case of writer's cramp if he will first acquire an understanding of the conditions to be treated and the indications present in the given case. It is simply the question confronting us in all practice, the question of meeting the indications with the right means. In former days it was the custom to describe mechanical methods as if the prescription for the case was a "method," regardless of individualizing as to dosage, actions, and the fundamentals of medical prescribing—especially of prescribing electric currents. But to-day emphasis need only be laid upon the indications. The practitioner must possess the knowledge acquired by study of how to make each and every "tool" he uses in either surgery or medicine do what he wants to make it do, and if he lacks this rudimentary knowledge he will not undertake an appendectomy and he ought not to undertake to set up alterative and nutritional actions in diseased tissues. If he does he will deserve to fail of the desired results.

But with this essential fundamental knowledge of physiological actions and how to produce them at will with selected resources of electricity, the practitioner can accomplish much with any of the modern appliances which will give him the means of dose regulation and quality of current action that these cases need. The writer has variously employed with success all the currents. The galvanic current, currents from fine high grade faradic coils, the great resources of static electricity, and high frequency apparatus can all be made to do the work demanded, provided the given apparatus has efficient therapeutic resources and the means of applying them.

In most cases it will be necessary to improve the quality of the blood as well as the circulation through the affected tissues, for anemia, if present, retards the regenerative processes. A "sedative-tonic" action is also indicated to allay irritability and remove aches and pains. Tonic contractions of the affected muscles are always needed but must be carefully "dosed" to avoid the reactions of fatigue. The physician who is well grounded in the ordinary principles of current-control, actions, and dosage can easily apply his knowledge to the relief and improvement of writer's cramp, and in early cases can rapidly restore the arm to normal endurance and comfort. The mental relief to the patient will be incalculable.

230 West One Hundred and Seventh Street.

Bacteriological Investigations in Cerebrospinal Fever.—An interesting report has just been issued by Dr. R. M. Buchanan, bacteriologist to the city of Glasgow, in connection with cerebrospinal meningitis. For some time past cerebrospinal fever "contacts" have been subjected to a systematic examination for evidence of the meningococcus, and for this purpose swabs have been taken of the secretion of the nasopharynx. The principal difficulty has hitherto been that in the throat there exist several organisms closely resembling the meningococcus, but Dr. Buchanan believes that he has now obtained a nutrient medium which serves to demonstrate the organism in the throats of a certain proportion of patients and "contacts" within two to three days. During the month of May eight cases of cerebrospinal meningitis came under bacteriological investigation for verification of the diagnosis, and in seven of these the meningococcus was demonstrated. The "contacts" examined during the month numbered 81, representing 20 families. In 12 of these families an organism was found in the throat, which had all the microscopical and cultural characters of the meningococcus. In five of the families it was found in one individual, in six of the families in two individuals, and in one family in three individuals—giving 20 positive results in the 81 "contacts." These results have principally been got in adults. In addition, the nasopharyngeal secretion of seven patients and four convalescents—all verified cases—was examined. The meningococcus was found in three of the patients on the twenty-third, twenty-sixth, and sixty-first days of illness respectively, and in all the convalescents on the seventeenth, thirty-fifth, fifty-sixth, and seventy-fifth day from the onset of their respective illnesses. These results serve to indicate that the disease may be carried and spread by individuals who offer no evidence of its presence and that it may remain for a long time in the throats of individuals who are recovering from the disease.—*The Lancet.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, January 18, 1908.

AN UNNECESSARY BILL.

A BILL purporting to be in the interest of humaneness has recently been drawn up for introduction at the present session of the New York Legislature. The promoters of the bill have been sending canvassers about among the members of the medical profession in this city endeavoring to obtain signatures to a petition favoring the passage of the measure. As the bill, on hasty reading, seemed to be moderate enough and devoid of oppressive features, a number of signatures were obtained, but we understand that many of these were withdrawn by the signers as soon as they appreciated the real significance of the movement. Even a medical contemporary was led to commend the measure editorially, but withdrew its support the following week. This is the only basis for the statement that the medical profession of the State is in favor of the proposed legislation, and the assertion that has been made that the New York physicians themselves drew up the statute is entirely erroneous. The New York physicians are opposed to it and the more they study it the stronger is their opposition.

It may not be known to all of our readers that the existing laws regarding the prevention of cruelty to animals, which seem to have been very wisely drawn, already constitute a safeguard against possible abuses. The law allows the performance of "any properly conducted scientific experiments or investigations, which experiments shall be performed only under the authority of the faculty of some regularly incorporated medical college or university of the State of New York." This law has proved sufficient for its purpose, and under it New York has advanced to the front rank among American centers of medical and scientific progress. Neither in the interest of humaneness nor on the part of the medical profession is any change in the existing law needed or desired, and we can conscientiously counsel our professional brethren to stand as a unit against lending their assistance to any such movement.

The measure now proposed is the more dangerous from its plausibility. It requires the licensing of all buildings in which animal experiments are to be performed, provides for semi-annual reports regarding the statistics and details of experiments, limits demonstrations, and places upon experiments a number of restrictions frequently demanded by the out-and-out antivivisectionists. Under the notion that the disposition of experimenters is such that they require restrictive control—a notion, the insulting character of which must be evident to every member of the medical profession—the bill offers barriers to medical progress. It should be strenuously opposed.

Especially should the argument be allowed no weight that the bill in question would forestall more radical and more dangerous legislation. It would inevitably pave the way, should it become a law, for other oppressive and more restrictive measures. Such an argument reveals only more clearly the insidious nature of the present attack. Here, as elsewhere, it is the first step that counts. The passage of the first antivivisection law in this State would mean the beginning of improper limitations which would have no end. The united effort of the medical profession is needed to prevent this first step.

THE TUBERCULOUS COW.

WHEN it was announced recently that 72 per cent. of all the herds of cattle in this State contained each one or several animals affected with tuberculosis, and that of 2,753 cows examined by the State Agricultural Department 22.8 per cent. responded to the tuberculin test, the statement was made by an official of the Health Department of this city that there was no special significance in the fact and that there was no danger of a contamination of the milk supply. This optimistic view is not shared by the officials of the Bureau of Animal Industry at Washington, who assert positively what everybody already knows, except apparently some health officials in New York, that there is "danger to public health so long as cows which react to the tuberculin test are allowed to furnish milk or butter for public consumption," and moreover furnish proof of the truth of their assertion.

In circular 118 of the Bureau of Animal Industry, entitled "The Unsuspected but Dangerously Tuberculous Cow," Dr. E. C. Schroeder urges the general application of the tuberculin test, and the immediate segregation of all cows found to react to it. He says little can be learned from the appearance of the cow, for many markedly tuberculous animals look and act like healthy animals; eating well, not emaciating, and presenting neither symptoms of disease nor signs of discomfort; yet they may be continually distributing tubercle bacilli in the saliva, milk, and feces. Even if the udder is not diseased and the milk therein contained is free from bacilli, the feces will be found to contain them in enormous numbers, and that a large proportion of milk furnished by all but the really "model" dairies—and now and then accidentally even by them—contains at least a minimal sediment of feces is microscopically, and often macroscopically, demonstrable. Straining dirty milk will remove some or all of the gross impurities, but it will not remove the free bacilli with which those impurities have contaminated it before their removal. Centrifugalization is much more effective than straining, as anyone with a strong stomach can learn for himself by visiting a creamery where this method is in use and examining the sediment so obtained. He will need a strong

stomach to drink ordinary milk after such a demonstration.

A tuberculous cow is, however, not only a contaminator of milk, but a menace to all the others in the herd. Dr. Schroeder says that the experiments made by members of the Bureau of Animal Industry show that the commonest way in which tubercle bacilli pass from the body of a tuberculous cow is with her feces. In every case of tuberculosis examined in which tubercle bacilli were being expelled they were found in the feces, and often when they could not be detected elsewhere. When we remember that the average cow passes about thirty pounds of feces a day, a large part of which falls in the pasture where the other cows are feeding, and the remainder in the cowbarn, it is difficult to see how the infection of the entire herd can be long delayed. The necessity of the tuberculin test, applied at least once a year, and of the immediate segregation of all animals reacting to it, is therefore apparent. Whether or not such an animal should be killed at once, or whether its milk should be allowed to be sold or the cream used for the manufacture of butter is a difficult problem. Undoubtedly the destruction of all tuberculous cows would lead to a milk famine, for the figure of nearly 23 per cent. of tuberculous cattle in New York State would probably hold or be exceeded in other States. If it were possible to keep the milk from such diseased animals separate from the general supply, to remove the fecal and other contamination by centrifugalization, and then to pasteurize the clean milk, it might be used with a measure of safety in the manufacture of butter or cheese, but it should not be allowed to mix with the general supply. The temporary shortage in the milk supply, would, no doubt, cause distress and raise the price for a time, but the decrease in tuberculosis would compensate for this, and a campaign of education would reconcile the consumers of milk to the temporary inconvenience. The natural increase in the healthy herds would soon bring the number of milk producers up to the normal. Then yearly tuberculin tests would serve for the detection of the disease in its early stages and prevent it from ever again prevailing to the present deplorable extent.

THE DANGEROUS EFFECTS OF ETHER AND CHLOROFORM.

No one can for a moment question the blessings which ether and chloroform have conferred upon suffering humanity. It is not necessary to dilate upon the fact that thousands upon thousands of lives have been saved through these beneficent agents, but one cannot either overlook the fact that both ether and chloroform are dangerous agents and that death has often followed their administration. But though a fatal issue from ether and chloroform is not a factor to be entirely disregarded (thus, for instance, according to the statistics of Gurlt one death occurs in 2,075 chloroform anesthesias) we do not desire to speak of this factor at the present moment, but would call attention to the injurious remote after-effects which so frequently follow the administration of chloroform and ether and which are generally overlooked. We seem to forget that both chloroform and ether produce a profound effect on the human organism and the effect may be permanent.

In subjecting the organs of patients who died from the effects of chloroform to a careful microscopical and pathological examination, B. Mueller (*Archir für klinische Chirurgie*, 1905) found that the most important organs of the body, such as the heart, lungs, liver, brain, and kidneys, underwent a fatty degeneration. He also found that ether possessed the same property of producing a fat metamorphosis, though in a milder degree, as chloroform. A dangerous fat metamorphosis which shows itself by the appearance of fine droplets of fat was found in the liver and kidney cells after a single prolonged chloroform anesthesia and also after one prolonged ether anesthesia. The pathological findings were in every way intensified if the anesthesia had to be repeated in twenty-four hours. Experiments on dogs yielded the same results. The idea that a mixture of various anesthetics is less dangerous than either chloroform or ether has also been shown to be erroneous. In fact, according to Mueller (*Deutsche medizinische Wochenschrift*, November 8, 1907) the after-effects of a mixture of anesthetics are even more to be dreaded because we have a combination of several toxic actions.

It is a mistake, therefore, to think that the inconvenience of ether and chloroform consists merely in nausea, vomiting, thirst, secretion of mucus, ether-pneumonia, etc., for the effects are more profound; and the opinion is gaining ground that many a fatty parenchymatous degeneration of the heart, liver, kidneys, etc., has had its starting point in a chloroform or ether anesthesia. It is for this reason, as well as on account of the danger of a fatal issue, that many men have been earnestly working for a substitute for general anesthesia by chloroform or ether. Thus there have been developed local anesthesia, infiltration anesthesia, regional anesthesia, hyoscine-morphine anesthesia, and spinal anesthesia.

General anesthesia by chloroform or ether will probably always be employed to some extent, but its field of usefulness will doubtless become more and more restricted. It is the duty of every surgeon who has the future as well as the immediate welfare of his patient at heart to consider the profound metamorphosis which chloroform or ether anesthesia may produce on the human organism, and so far as possible and whenever feasible to select one of the less dangerous methods of inducing anesthesia.

Bilateral Nephrotomy in Calculous Anuria.

In calculous anuria the all-important thing to do is to relieve the anuria, whether there is a unilateral or bilateral calculus present. In unilateral calculus with anuria the diseased kidney is usually cut down upon, but often this does not relieve the anuria, a fact to which F. S. Watson draws attention in the *Annals of Surgery* for September, 1907. He advises bilateral nephrotomy in those cases in which the entire calculous kidney is destroyed, it being clear that the operation on one side will not secure any compensating advantage as regards the urinary

secretion; in such cases the secretion, which took place before the anuria set in, was effected in the other kidney, and therefore a relief of this condition can be caused only by cutting into this kidney. In cases in which the calculous kidney is not entirely destroyed the question as to whether the remaining liberated renal tissue is sufficient to relieve the anuria becomes more difficult to decide. He reminds us that a very small amount of healthy tissue is capable of sustaining life after having been freed of its obstruction, and therefore it is frequently not necessary to do a nephrotomy of the other kidney in cases of noninfected hydronephrosis. On the other hand, with infected renal retention of calculous origin, a well-marked infection will render unfit for service what appears to the eye to be a considerable amount of renal substance, and Watson therefore advises cutting into both kidneys in infected cases with anuria. In the presence of bilateral renal calculus he advocates bilateral nephrotomy at one sitting, unless the patient's condition is such as to make the long time required for operating on both kidneys an obviously improper danger to which to submit him. He relates the history of several patients upon whom this was done with good result. The advantage Watson claims for this procedure is that neither kidney is subjected any longer to the destructive influence of the calculus, and that he has thus liberated all the functionally capable renal substance which is possessed by the individual, all of which he usually needs.

Paresis and Tabes in the Colored Races.

By means of the ingenious method of fixation of the complement Wasserman has been able to show that in a very large proportion of the cases of paresis and tabes there is a definite indication of a previous syphilitic infection. Although these results as yet lack sufficient confirmation to be regarded as firmly established, and it is by no means certain that syphilis is a forerunner of every instance of these diseases, it is likely that this line of investigation will prove very fruitful in clearing up the etiology of these maladies of civilization. It has long been understood that the comparatively carefree existence enjoyed by the natives of countries whose state of culture secures them immunity from the mental stress that attends the higher degrees of intellectual development are rarely subject to these two diseases, and this fact has often been used as an argument in favor of the view that syphilis alone is not responsible for their causation. The greater interest now being taken in the demography of the tropics promises to aid in clearing up this as well as many other questions, and recent writers are confirming what has already been alleged on more or less hearsay evidence. Ziemann, for example, (*Deutsche medizinische Wochenschrift*, December 26, 1907), who has had much experience in Africa and tropical America, has found that while syphilis is especially common in these latitudes, the nervous diseases in question are exceedingly rare among the natives, and Baelz, who spent thirty years in Japan, has said that, though syphilis was prevalent in that country, general paralysis was seldom seen until within recent years, when the intellectual attitude became more nearly like that of the white races. There seems little doubt that syphilis can at most be only the predisposing factor in the etiology of these diseases, and that other elements, among which that of undue or unnatural mental activity is prominent for paresis at least, also enter into the question.

Vaginal Varicosities in Pregnancy.

Among the earliest and most constant signs of pregnancy is the dark bluish or purplish coloration of the lower portion of the vagina, sometimes known as Jacquemier's or, in this country, as Chadwick's, sign. It depends, of course, on the circulatory disturbances attending the changes in size and position of the uterus, and may, therefore, also accompany other conditions in where there is enlargement of this organ. Not infrequently the dilatation of the veins becomes extreme and true varicosities are formed. The proportion of cases in which this takes place is variously stated by different authors, probably owing to a lack of a definite standard for determining what shall be considered as varicosities, but is certainly far from low; Kehrer, for example, affirms that varicosities in one situation or another are found in 75 per cent. of all pregnant women, and that over 25 per cent. of these involve the vulva. While ordinarily the presence of such venous dilatations is the source simply of a certain amount of discomfort to the patient through the itching, feeling of fullness, etc., that they occasion, the danger of rupture is always present and involves serious risk to life. Three cases in point are reported by Grünebaum in the *Münchener medizinische Wochenschrift*, December 24, 1907, the immediate cause of the hemorrhage being in one case trauma through the entrance of a foreign body into the vagina, in another coitus, while in the third rupture of the varicosities apparently occurred spontaneously. This latter patient, in the eighth month of pregnancy, was found lying dead on the floor bathed in blood. One of the others fell from a wagon in such a way that a stake entered the vagina, and, though medical aid was obtained without great delay, the loss of blood was sufficiently severe to cause the patient's death two days later. In the third instance coitus during the seventh month gave rise to a copious hemorrhage which was controlled by packing and ligature, the woman recovering. While such cases are unusual, the danger is none the less a real one, and pregnant women should always be warned of the possibility of accidents of this kind and be instructed as to the measures to be resorted to while the physician is being summoned.

The Material Position of the Medical Man.

The position of the medical man everywhere is not improving, if we look at it from the pecuniary standpoint. In America the excessive competition among members of the medical profession tends to keep the average earnings of the ordinary general practitioner at a low limit, and there are various other causes which fight against the medical man. Perhaps the greatest obstacle in his path, after all, is the ever-increasing scope of preventive medicine. In Great Britain the situation in this respect is very similar to that of this country. Dr. William Ewart, speaking recently at the opening of the winter medical session of St. George's Hospital, London, drew attention to the fact that specialization was spreading and the field of general practice was contracting, and the reason for all this was largely found in the results attained through the instrumentality of preventive science. He predicted that at the present accelerated rate of prevention there would soon be little left of preventable disease to attend, and he went on to say that the altered conditions of life must tell upon

local practice, whether in town or country. The reward a man gets for a large expenditure on his training and years of faithful study only averages from £200 ($1,000) to £300 ($1,500) per annum. All this is perfectly true, the province of the physician is becoming less to cure, but more to prevent disease. In the interest of public health such a consummation as the gradual stamping out of disease is one much to be desired. The medical man will still be needed and must in the nature of things play a prominent part in bringing about this hoped for result. In the meantime, and probably so long as the world lasts, his services will be required in the curative and remedial sense, although in these respects undoubtedly they will be greatly curtailed. He must adapt himself to the new conditions and can only ask for more fair play than is accorded him at the present time.

News of the Week.

Amendments to the Sanitary Code.—At last week's meeting of the Board of Health Section 159 of the Sanitary Code was amended so as to provide that all physicians and midwives "shall file with the Board of Health reports of all births at which they assist, within ten days of same." The change was made to prevent the loss, or alleged loss, in the mail of the reports, which it was formerly permissible to send in by post. Another section amended was No. 42, which provides that no unwholesome food should be brought into, stored, or offered for sale in the city and was amended by adding the provision that "any foods offered for sale anywhere in the city by dealers in food shall be deemed to be offered or held for sale as food."

Summer Resort Hotels.—The report of State Health Commissioner Porter, issued on January 8, shows that of sixty-four summer hotels and boarding-houses in the Catskills and Long Island inspected during a month, forty were found above reproach as to water supply, plumbing, and methods of sewage disposal. The remaining twenty-four showed undesirable conditions in these lines, and some were badly kept, had dirty kitchens, and outbuildings generally unclean. These cases all have been taken up by correspondence with the proprietors and requests made that the particular offense charged against the hotel be remedied before the opening of the next season. If at that time it is found that the remedies advised have not been adopted the department announces its intention of so informing the public.

Occupational Diseases in Illinois.—Governor Deneen has appointed the following named physicians on the committee of nine authorized by the General Assembly for the purpose of investigating occupational diseases in the State and submitting a report to the next General Assembly, viz., Dr. Ludvig Hektoen, pathologist Rush Medical College; Dr. George W. Webster, president State Board of Health; Dr. James A. Egan, secretary State Board of Health.

State of Health in Chicago.—According to the weekly bulletin of the Chicago Health Department, in the month of December there were 2,704 deaths reported, equivalent to an annual death rate per 1,000 of 15.10. Chief among the death causes were: Pneumonia, 447; consumption, 278; heart disease, 237, and violence, including suicide, 218.

Death Rate in New York City.—During the first week of the month there died in this city, according to the Health Department, 1,561 persons, or 156 less than last year, the rate being 18.46, as against 20.95. There were notable decreases in the number of deaths from pneumonia, tuberculosis, and heart disease.

Eleven Cases of Caisson Disease in One Night.—On one night of last week eleven workers in the compressed air locks of the Long Island City tunnel were taken with the "bends" as they emerged after a night's shift. They were quickly taken to the hospital air lock, and all recovered except one who had been engaged in such work for five years and was considered immune to the disease.

Railroad Deaths.—In its twenty-first annual report issued on January 6 the Interstate Commerce Commission states that the total number of passengers carried by the railways during the year ending June 30, 1906, was 799,507,838, and on the above date the number of employees on the payrolls of the companies was 1,521,355. During the year ending June 30, 1907, 647 passengers and 4,353 employees were killed and 13,597 passengers and 62,689 employees were injured.

Royal Invalids.—The Czarina is reported as being very ill as the result of a vigorous anti-obesity cure followed by an attack of grip. The condition of the Japanese Crown Prince, who is tuberculous, is said to be causing grave anxiety, and Professor von Baelz, a German physician, who has spent many years in Japan, has been sent for to consult with the Japanese medical men. The Crown Prince is twenty-nine years of age and has three sons.

Plague in China.—The epidemic of bubonic plague at Teng-chow-fu, province of Shan-tung, has been checked, apparently by the advent of cold weather. It caused over 100 deaths. The authorities are taking precautionary measures against an outbreak along the coast in the spring.

Smallpox in Immigrant Ship.—The Russian steamship *Moskva,* from Libau and Rotterdam, was held at Quarantine on January 9 because one of her steerage passengers, a woman, had died at sea of a disease resembling smallpox. All the steerage passengers were transferred to Hoffman Island for observation, and the steamship was disinfected.

Radium Baths in Austria.—The Austrian government has decided to establish radium baths on a large scale at Joachimsthal, at present the most productive source of radium known. The municipality of Carlsbad and an English syndicate have been attempting to obtain control of the deposits, but the government has decided to retain all rights, partly as a source of revenue and partly from the standpoint that so important a therapeutic institution should be under State supervision.

Study of Cancer of the Breast.—Dr. Horace Packard, 470 Commonwealth avenue, Boston, Mass., desires information regarding any alleged recoveries or cures of inoperable or recurrent carcinoma of the mammary gland. If any case or cases are known to any reader of this request and can be authenticated by facts as to the history and condition prior to recovery and the length of time which has elapsed since recovery, such information will be much appreciated and duly acknowledged. Any well-authenticated reports of recoveries from carcinoma located in other parts than the mammary gland will be welcome. Cancer paste cures, *x*-ray cures, radium cures, or cures as result of surgical operation are not wanted. Hearsay cases are not wanted unless accompanied by name and address of person who may give knowledge first hand.

Tuberculosis Exhibition.—The exhibit of the Committee on the Prevention of Tuberculosis of the Charity Organization Society, which has been at the Jamestown Exposition, was last week opened to the public in a store lent by the Metropolitan Life Insurance Company in its building in East Twenty-third street.

City Fire Gongs to Be Removed from Hospitals.—The fire gongs giving the location of fires occurring in the various districts, are to be removed from the city hospitals that have them, as they are not considered necessary. These were installed with the idea that ambulances should be sent to fires in the neighborhood of the respective hospitals, but it has become customary to wait for the usual police call before sending out the ambulances. The alarm boxes for the purpose of summoning the fire department in case of fire in the hospitals will, of course, be continued.

Organization to Urge Canteen Restoration.—The governing board of the Army Canteen Association, recently formed to create sentiment in favor of the restoration of the canteen at army posts, at a meeting held in this city last week, decided to establish similar organizations in every State in the Union. Branches are to be formed in all large cities and an active campaign will be conducted in behalf of a bill to be presented to Congress providing for the reestablishment of canteens at army posts and soldiers' homes.

City Hospital Changes.—Plans have been filed for extensive improvements on Blackwell's Island and Randall's Island. These comprise for Blackwell's Island a four-story tuberculosis pavilion, with roof gardens, solarium and exterior verandas, to cost $180,000; a one-story and attic hospital pavilion for the City Home for the Aged and Infirm to cost $75,000, a two-story pathological laboratory to cost $40,000 and a three-story and attic residence for the medical staff to cost $80,000. All these buildings are to be grouped about the Manhattan Hospital, of which they are to be annexes. The fifth projected improvement is a four-story home for the nurses attached to the Children's Hospital on Randall's Island, which is to cost $200,000, making a total of $575,000 to be expended on the five buildings.

To Enlarge Chicago Hospital.—A movement is on foot to enlarge the Hospital of St. Anthony of Padua at a cost of approximately $100,000, the addition to include a five-story building, 50x115 feet, with a rear wing of 38x50 feet.

Illinois State Board of Health.—At the thirty-first annual meeting of the Illinois State Board of Health the following officers were elected during the morning sessions: *President*, Dr. George W. Webster of Chicago; *Secretary and Treasurer*, Dr. James A. Egan of Springfield. This is the twelfth time Dr. Egan has been elected secretary of the State Board of Health.

Annual Meeting of Visiting Nurses of Chicago.—According to the report presented at the annual meeting of the Visiting Nurses' Association by Miss Harriet Fulmer, superintendent, 14,081 cases were cared for during the year, of which 1,137 were tuberculosis and 464 scarlet fever.

Lavoisier Medal.—The Lavoisier medal of the Paris Academy of Sciences has been awarded to Professor Adolf von Baeyer of Munich in recognition of his work in organic chemistry.

Dr. George T. Jackson has been made professor of dermatology in the College of Physicians and Surgeons, Columbia University, to succeed Dr. George H. Fox, resigned.

Death of a Surgeon at the Operating Table.—Despatches from Berlin state that at an operation in the Birkenfeld Infirmary, the surgeon, who was operating on a child, died suddenly of heart disease. Before another operator could complete the work the patient died.

The Suggested Vivisection Bill.—Letters have been sent out from the College of Physicians and Surgeons, the University and Bellevue Hospital Medical College, Cornell Medical College, and the New York Post-Graduate Medical School and Hospital, to all the officers of these institutions urging them not to lend their influence in favor of the bill to regulate vivisection which it is proposed to bring before the State Legislature at the present session.

Blue Earth County (Minn.) Medical Society.—At the meeting of this society, held on January 2, the following officers were elected: *President*, J. A. Hielscher; *Vice-President*, Dr. J. T. Schlesselman of Good Thunder; *Secretary*, Dr. T. C. Kelly of North Mankato; *Treasurer*, Dr. Lida Osborn.

New London (Conn.) Medical Society.—At the annual meeting of this organization held on January 2 officers were elected as follows: *President*, Dr. E. A. Henkle; *Vice-President*, Dr. Daniel Sullivan; *Secretary and Treasurer*, Dr. H. H. Hyer; *Librarian*, Dr. F. W. Howes. The address of the evening on tuberculosis was delivered by Dr. James E. Newcomb of this city.

Dallas County (Ala.) Medical Association.—This society elected the following officers at its meeting held in Selma on January 1: *President*, Dr. S. Kirkpatrick; *Vice-President* Dr. S. Alison of Carlowville; *Secretary*, Dr. B. B. Rogan; *Treasurer*, Dr. C. Ritter.

Death of Dr. Lassar.—Professor Oskar Lassar of the University of Berlin, a dermatologist of international eminence, died on December 23 at the age of fifty-eight years.

In Memory of Dr. Shrady.—The following minute was adopted at the meeting of the New York Pathological Society held on January 8, 1908:

It is with deep regret that the New York Pathological Society has to record the death of its late member, Dr. Geo. F. Shrady, on November 30, 1907.

Dr. Shrady became a member of the society in 1858, and, after thirty years of service as an active member, was in 1888 duly elected an honorary member of the society. During the time of his active service he served the society as president during the years 1883 and 1884 and as secretary from 1861 to 1879, a period of eighteen years.

During the time of his service as an officer of the society he always had the respect of its members and was ever faithful in the discharge of his duties. By his death the society has to mourn the loss of a faithful member and officer.

(Signed) Geo. C. Freeborn,
George P. Biggs,
Committee.

In Memory of Dr. Loomis.—The Board of Trustees of Bellevue and Allied Hospitals adopted the following resolution at its meeting held on December 31, 1907:

Whereas, The Board of Trustees of Bellevue and Allied Hospitals has learned with profound regret of the death of Dr. Henry P. Loomis, for many years one of the attending physicians to Bellevue Hospital, be it therefore

Resolved, That the Board desires to place on record its sense of the value of Dr. Loomis' services to the patients he has treated within the walls of Bellevue Hospital, as well as his more extended services to the cause of medical science in general; and be it further

Resolved, That copies of this resolution be forwarded to his family and to the medical journals of the City of New York.

True copy of resolution adopted at meeting held on December 31.

J. K. Paulding,
Secretary Board of Trustees.

Obituary Notes.—Dr. S. F. Pomeroy of Springfield, Mass., the father of Dr. William H. Pomeroy, died on January 11 at the age of eighty years. Dr. Pomeroy was graduated from Yale Medical School with the class of 1855 and had practised in Springfield for more than fifty years.

Dr. Levi Jewett of Cobalt, Conn., died of pneumonia on January 3 at the age of seventy-two years. Dr. Jewett was a native of Griswold and received his medical education at the Bellevue Hospital Medical School. He practised for a time in Windsor Locks and then served through the Civil War as assistant surgeon and at the time of his death was medical director of the Connecticut Department of the G. A. R. In 1905 he was made a member of the Legislature from Chatham. Mrs. Jewett died of the same disease five days after her husband.

Dr. W. H. Giddings of Bakersfield, Vt., died on January 3 at the age of sixty-seven years. Dr. Giddings was born in Bakersfield and was graduated from the medical school of the University of Vermont in 1866. He practised in his native town until 1892, when he was made superintendent of the Vermont State Hospital for the Insane, holding the position for several years. In 1880 he represented his town in the Legislature.

Dr. John Boice of Denver, Col., died on December 28 at the age of sixty-eight years after an illness of ten days from grip. He came to Denver from Detroit eighteen years ago and for a long period was connected with the Gross Medical College.

Dr. Thomas E. Williams of Hanover, Va., lost his life at the age of seventy-two years in a fire which destroyed his home on December 31. He was a native of Maryland and served through the Civil War in a Maryland regiment. At the close of the war he began practice in Hanover County and continued there until failing health compelled him to retire a few years ago.

Dr. William L. Coleman of Salina, Kan., died suddenly on January 2 at the age of seventy-two years. He was born in Illinois and served in the Civil War in the One Hundred and Third Illinois Infantry, being discharged in 1863 owing to disability due to a bullet wound received in the battle of Missionary Ridge. He then practised in Chicago, moving to Salina about five years ago.

Dr. Philip J. Strathy of Toronto, Can., died suddenly on January 2 at the age of forty-two years. He was a graduate of Trinity Medical College and was on the staff of the Toronto General Hospital.

Dr. James F. Moliere of San Francisco died of pneumonia on December 28 at the age of eighty-one years. He had practised for many years in San Francisco and other California cities.

Dr. Calvin A. Wetmore of Catskill, N. Y., died on January 12 at the age of seventy-six years. Dr. Wetmore received his diploma in the early fifties from the Berkshire Medical College and had practised for twenty-six years in Emporia, Kan.

FOURTH HARVEY SOCIETY LECTURE.

The fourth of the present series of lectures held under the auspices of the Harvey Society, was delivered at the Academy of Medicine on Saturday evening, January 11, by Professor Ernest H. Starling, of the University of London, the subject being "The Chemical Control of the Body."

For ages, the speaker said, man had been seeking to obtain the same control over the actions in his body which he had succeeded in obtaining in the inanimate world about him. He had long recognized that he could profoundly influence the body by means of chemical substances, or drugs, as they were called. But the art of drugging had been almost wholly empirical, and this had led to the well-known satire that most of our medication consisted in the "pouring of drugs of which we know little, into a body of which we know less." However, the art of drugging was gradually being placed on a scientific basis, and the speaker hoped to show some of the more recent conceptions which were guiding the development of the subject. He would begin by illustrating the employment, by the body itself, of chemical means for bringing about physiological processes at a distance. It was well-known that in the digestion of food, the various juices must be poured out in proportion to the amount of food to be digested, and at the time when the food is present in the organ. It had always been felt that the mechanism for regulating this was a nervous reflex. But it was found, even when the vagus was cut, that the introduction of some acid chyme into the duodenum caused a flow of pancreatic juice. Pavlov thereupon conceived the idea that there were nerve reflexes direct from the duodenum to the pancreas. However, when the question was studied by the speaker, the entire matter appeared in a different light. In the experiments which he made, all the nerve connections between the duodenum and pancreas were cut, leaving only the blood-vessels as a bond between them. When now the acid chyme was introduced into the duodenum, the reflex occurred just as before. The conclusion forced upon him, therefore, was that the massenger from the duodenum to the pancreas traveled by way of the blood-vessels, and was a chemical substance. It was natural to think that it was the hydrochloric acid in the chyme which acted in this way. But when this was injected in the vessels to the pancreas, no reflex action was produced in that organ. After a number of experiments, it was found that when the cells of the upper part of the duodenum were scraped off, and this mass mixed or boiled with hydrochloric acid, there resulted a substance which, when injected into the pancreatic vessels, at once caused the production of pancreatic juice. Evidently a peculiar substance was involved, for not only did it withstand boiling, but it was soluble in alcohol, and was readily diffusible. It did not give the reactions for protein with the ordinary reagents. Evidently it was a substance of small atomic weight. It had not been possible thus far to obtain it in a pure form, as it was highly oxidizable. From what had just been said it was quite evident that this could not be a haptin in Ehrlich's sense. This chemical messenger was but one of a number of such substances which the speaker had discovered. He had termed them collectively "hormones."

The hormone just discussed acted on three different organs at once, the liver, pancreas, and the intestine. In the latter it caused the production of succus entericus. This showed that there was an

economy of mechanism. This gut hormone had no effect in the stomach or in the mouth.

The speaker then went on to say that it could readily be understood how this hormone action could cause an accurate coordination between the amount of food to be digested and the amount of pancreatic juice poured out by the gland. The pancreatic hormone, as had just been shown, was produced by an interaction of the acid and the duodenal cells. When, then, there was an influx of acid chyme into the duodenum, the hormone was at once produced, and this led to the reflex actions in the pancreas and the other organs. As soon, however, as the alkaline intestinal juices had neutralized the chyme, the production of hormone ceased, and with it, of course, the reflex production of pancreatic juice.

Hormone actions, the speaker said, were not confined to the alimentary tract. We all knew that the contracting muscle was always supplied with just the amount of oxygen needed for its work. This was very simply regulated through the respiratory center. Just as soon as the contracting muscle began to send into the blood stream more carbon dioxide than before, the respiratory center began to signal to the respiratory apparatus to do more work, thus at once sending more oxygen to the working muscle. This carbon dioxide was a typical hormone.

There were other examples of this kind of action, but the reflex character of the mechanism was not so pronounced. Thus we knew that atrophy of the adrenal glands caused the complex of symptoms known as Addison's disease, with its vomiting, bronzing of the skin, and weakness. Subsequently it had been shown that a chemical substance of rather simple constitution could be derived from the adrenals, and this substance, adrenalin, acted particularly on the sympathetic nervous system. Adrenalin should be classed as a hormone. The Pituitary body also had some such action, as was shown in the overgrowth of bone, acromegaly, which was associated with affections of this organ. The thyroids were likewise of this class, and the substance iodothyrin which could be made from these glands was to be regarded as a hormone.

Prof. Starling then spoke of the action which the sexual organs exerted on the body, and alluded to the well-known effect of castration. There was also a marked correlation of the mammary glands and pregnancy. Prof. Starling had carefully studied this, and found that it was due to a hormone mechanism. In the rabbit the mammary glands began to grow with the beginning of pregnancy, and they continued to grow as long as pregnancy lasted. They did not secrete any milk, and yet regularly, two or three days after the termination of the pregnancy, the flow of milk began. His experiments had shown that this was not a nervous reflex, but was a hormone action. In order to determine where this hormone originated, he had injected a virgin rabbit with sterile extracts of placenta, uterus, or fetus from pregnant rabbits, and had found that the hormone in this case was derived from the fetus. The speaker then showed some pictures of the mammary changes induced in a rabbit by pregnancy, and in a virgin rabbit by injections of fetus hormone. After injections from over 150 fetuses the changes in the virgin rabbit about equaled those in a rabbit pregnant nine days. The speaker called attention to the difference between the continuous injections of hormone taking place normally in pregnancy, and the relatively few injections which it was possible to make in an experiment.

In conclusion, Prof. Starling admitted that the knowledge thus far obtained regarding these hormone actions was not of much practical applicability, but he thought we might look forward to increasing the power of control over our bodies if we worked further along these lines. He felt that at the present time no field was more promising of future success than was this one.

After a vote of thanks had been moved by Prof. Lee, the chairman announced that there would be two changes in the program of the lectures. It had been found impossible for Prof. Schäfer to be here for the lecture in April. His lecture would therefore be postponed until May 9. The other change was the announcement of an additional lecture, to be given by Prof. Alonzo Taylor, of the University of California. This would be given in March, but both date and subject would be announced later in the medical journals. The next lecture will be delivered on January 25, the speaker to be Dr. George W. Crile, and the subject of his lecture, "Shock."

Correspondence.

A MODERN CORNARO.

To the Editor of the Medical Record:

Sir:—Thank you for the note of sweet reason that rings through your editorial on the subject of Fletcherism in the Medical Record for January 4. If we eat only when we are hungry, the boy will devote most of his time to eating, and that will interfere with his preparation for the sciences and the humanities. If we expend a very long time in "divine mastication," a valuable part of the day will have to go to the profit and loss account, for the determination of blood to the digestive organs at meal times interferes with the higher cerebration. Imagine Sir John Lubbock proving that life is a beautiful gift, while he gravely chewed a cracker for an hour; or Schopenhauer proving that life is a great mistake, while slowly chewing the rag. Bringing the matter down to one of comparative physiology, which animals are the healthiest? Why, the ones that bolt their food, to be sure. Look at the hog, or the dog, or the bear.

One must not forget the psychic effect of a determination to get well and strong under any kind of system whatsoever. For an object lesson, note the Christian Scientists, or the Dowieites, or the followers of any historical movement of the same sort. Or for exhibit No. 2, look at the sanatoriums. Are there many in which the physicians make more than a shallow pretense at finding the real causes for a neurasthenia? Do they look for eyestrain, or for loose kidneys, or involuting appendices, and the various well-known leaks below the water line? Not at all! They depend upon the psychic influence of the environment for getting up the patient's steam, or filling his sails. That is why these patients are successfully cured so many times in a year.

It is a comfort to have your explanation that Fletcher's system probably belongs to his own system, and that we are not obliged, in order to be up-to-date, to inflict the system upon our patients, or even in extreme cases upon ourselves.

The doctor with deficient circulation goes on his rounds just now with a heavy overcoat and woolen underclothing. He advises every patient suffering from a psychosis or from corns to dress in the same way if he would be well. On the other hand, the doctor with vigorous circulation runs about without an overcoat, and with thin underclothing, and advises these same patients to wear the same things that he does, and not to forget to throw the window wide open at night.

There is no doubt that Chittenden is right in showing the dangers of an intake of proteids greater than we can safely manage, and that Fletcher is right in pointing out some of the dangers of rapid eating, but if the matter is to be reduced to a system, and the system is to be fired at us for a flock shot, it is profitless philosophy.

Robert T. Morris.

616 Madison Avenue.

DOMESTIC PETS AS ACTIVE CARRIERS OF INFECTIOUS MATERIAL.

To the Editor of the Medical Record:

Sir:—An hypothesis of the relation of human disease to disease affecting the lower animals, is by no means a gratuitous one; on the contrary, it has much to recommend it. Thus the communication of bubonic plague, diphtheria, smallpox, scarlet fever, measles, and other infections and contagions from the lower animals to man has long ago been established.

Now, the various orders of animated nature are so interdependent in regard to causation and spread of disease, that it appears unwise to limit our investigation to any one family or class. Without a clear comprehension of the factors that produce disease in individuals, attempts at prevention must be what a great deal of our so-called preventive medicine is—a mere sisyphusian waste of time. That diseases are not infrequently traceable to the lower animals such as cats, dogs, the various species of the feathered tribe, or the so-called house pets and household pests (rodents) is unquestioned. Indeed, on account of the filth endangered by the so-called domestic animals with their attendant parasites (fleas, etc.), the German government has promulgated rules whereby no domestic animals such as cats and dogs can be tolerated in a pharmacy, for every detail of the practice of pharmacy, especially in the larger cities, is closely supervised by the German government.

Some curious facts showing that the so-called domestic animals are carriers of contagion are recorded in the sustained prevalence of diphtheria in Enfield, Eng., by Dr. Bruce Low of the local (British) Government Board. He incidentally states, says the Sanitary Record, that during December, 1887, and January, 1888, there was a large mortality among cats. The following incident occurred at Enfield at the time, and shows the possible connection between diphtheria in children and in cats. "A little boy was taken ill with what turned out ultimately to be fatal diphtheria. On the first day of his illness he vomited, and a cat which was in the room at the time licked the vomit from the floor. In a few days (the child meanwhile having died) the animal was noticed to be ill, and her sufferings, being so severe and so similar to those of the dead boy, the owner destroyed her. During the early period of its illness the cat had been let out at night in the back yard as usual. A few days later, the cat of a neighbor who lived a few doors away was noticed to be sick. It had also been let out in the back yard at night. The second animal was a pet and playfellow of four little girls, who, grieved at the illness of their favorite, nursed it with great care. All four girls developed diphtheria, the mother being convinced that they got it from the cat; indeed, no other known source of contact with infection could be discovered."

Dr. Mason, the Port Medical Officer at Hull, Eng., in his official report as to the origin and outbreak of bubonic plague on board the steamship *Friary* at her dock at Hull and there held in quarantine and thoroughly fumigated, where she arrived with a cargo of cotton, January 10, 1901, says: "I am of the opinion that the probable cause of the malignant outbreak was a cat, which went aboard at the Port of Alexandria (Egypt) and which showed signs of illness during the voyage. It had frequented the forecastle occupied by the sailors. Of the nine sailors taken with the plague, eight of the victims succumbed to the attack. The mortality was confined to the men who lived in the forecastle of the ship, and to these only. The ship had twenty-one hands all told, with clean bills of health from Alexandria and Algiers, where she had touched. Ships had been arriving regularly in Hull from Alexandria with clean bills of health and the plague was not believed to exist there, or at the Port of Algiers, which also had been declared to be free from the plague. There was no outbreak of the plague in Hull proper. The bodies of three rats, afterwards discovered in the hold of the ship, were sent to Yorkshire for bacteriological examination. They were found, however, not to be affected with the plague."

In 1886 Dr. George Turner, Medical Officer of the local Government Board, stated to the writer that in the village of Braughing, Eng., diphtheria was prevalent at a farm among the fowls. A man from a neighboring village bought a chicken from an infected farm; he took it home, and diphtheria broke out in the house shortly after. This was the first case in that village. Dr. Turner further stated that his attention was called to these facts by the medical attendant, and the man himself corroborated the information in all particulars.

Similar accounts are received from abroad as well as in this country, as to the identity and transmissibility of disease from the lower animals such as have been observed in swine, sheep, dogs, horses, and cattle, to human beings. I may here incidentally state that hair, fur, wool, and feathers are carriers of infectious material.

I am encouraged, therefore, to be content with drawing attention to the danger from infected domestic animals such as cats and dogs, whose ratting and mousing propensities and other habits render them especially liable to infection.

William B. Meany, M.D.

New York.

OUR LONDON LETTER.

(From Our Special Correspondent.)

CONTROL AND PREVENTION OF PLAGUE—OBITUARY, PROFESSOR ANNANDALE AND SIR P. H. WATSON.

London, December 27, 1907.

Preventive medicine in relation to plague is very much to the fore with the intelligent public as well as the profession. This is as it should be with the great calamity of India before us. Sir George Clarke, Governor of Bombay, has addressed himself to the subject in a most enlightened way, visited the districts where the epidemic rages and investigated for himself the process of manufacture of the prophylactic, so as to be able to assure the suffering people that they are altogether mistaken in regarding the injections as dangerous or as otherwise than most beneficial. He has also sent a circular letter to the native journals in which he asserts that "if all the people in infected areas would be inoculated the plague would quickly disappear." The *Times of India*, in commenting on the Governor's letter, makes the excellent suggestion that the editors of the vernacular journals should be invited to visit the laboratory and see for themselves the process of manufacture as to learn for themselves the truth and help to remove the suspicions and ignorance of their readers.

A paper on the control of the plague has been contributed to the Epidemiological Section of the Royal Society of Medicine by Mr. Haffkine. He pointed out how it is that previous efforts to deal with epidemics have been so largely unsuccessful. Treatment of the sick, disinfection, evacuation of infected areas, destruction of rats, and so on, are not without some effect, but cannot be relied on, for they cannot be carried out with absolute completeness or else they only deal with minor factors. This is why immunity should be conferred on the population in the manner that vaccination confers it against variola. This is to be obtained by Mr. Haffkine's prophylactic, as experience has shown that (1) in a native of India who was more susceptible to plague than Africans, Europeans, and some other races, the inoculation reduced the liability to attack to less than one-third; (2) in one-third of the cases which still occurred the rate of recovery was at least double that in the noninoculated, the ultimate result being a reduction of mortality of 85 per cent.; (3) in an inoculated European if attacked recovery always occurred, so far as the author knew; (4) inoculation of those already affected or incubating plague prevented or mitigated the attack, a fact which discloses a basis for the bacteriotherapeutic treatment; (5) in natives the degree of immunity conferred, though gradually vanishing, seemed to last during several outbreaks; on Europeans the effect has not been seen to disappear during the time that has passed since the inoculation method has been under investigation, *i.e.* from 1897.

Another paper was read by Dr. Ashburton Thompson, the head of the Public Health Department of New South Wales. He dealt with the part of the statesman in preventing the disease. When a community is faced with an outbreak of plague it is not his part but rather that of the administrator to deal with it, and the only means of doing so are the immunization of the people, which Mr. Haffkine's genius has made possible, evacuation of the locality, and the destruction of rats. These measures, Dr. Thompson said, are remedial and not truly preventive. Consequently they may have to be repeated when another outbreak occurs. The arrest of present outbreaks is quite a different matter from the diminution of the liability of a country to suffer them. This last is the statesman's business. It is the rat-flea which carries the infection. As we cannot completely exterminate rats we must render all occupied buildings rat-proof, and this, says Dr. Thompson, is the only method to which the term "preventive" can be applied with correctness. Every building rendered inaccessible to rats is a fortress impregnable to the enemy. This shows the road the statesman must take. The difficulty of saving a people from attack is proportioned to that of rendering their habitations rat-proof. Further, the difficulty of clearing a place of plague is propor-

tioned to that of removing the harborage of rats in the mouths of sewers, in heaps of rubbish, dilapidated sheds, and the like. The problem of eradicating the plague thus put forward is one that extends over vast periods, and it must be acknowledged that in Dr. Thompson's opinion no speedy exemption is to be expected.

Edinburgh has lost two of her most eminent surgeons and teachers by the almost simultaneous death from cardiac failure of Professor Annandale and Sir Patrick Heron Watson. The former was found dead in his bed on Friday morning and his colleague died on Saturday. They lived within a few doors of each other.

Thos. Annandale, F.R.S.E., Regius Professor of Clinical Surgery, was an Honorary Fellow of the English College of Surgeons as well as that of Edinburgh, and a member of numerous medical societies, Surgeon to the Royal Infirmary, the Children's and other hospitals. In early days he was Demonstrator of Anatomy at the University and took the gold medal for his graduation thesis on "Injuries and Diseases of the Hipjoint." He also took the Jacksonian prize of the London College of Surgeons for his essay on "The Malformations, Diseases, and Injuries of the Fingers and Toes, and Their Surgical Treatment." With such a beginning he passed rapidly to the highest surgical posts in the University and Infirmary. He was made Surgeon-General to the Queen in Scotland and received honors from various surgical societies at home and abroad, including the honorary fellowship of the American Surgical Association. Dr. Annandale was in his seventieth year and the day before his decease seemed in his usual health and operated in the Infirmary. In this the two deaths did not resemble each other, as Sir P. H. Watson had been out of health for some time and in some quarters his death was anticipated.

Sir Patrick H. Watson, who had attained the age of seventy-five, took the M.D. (Edin.) in 1853 and two years later F.R.C.S. (Edin.). He served as Assistant Surgeon in the Crimea and received the Crimean, Sardinian, and Turkish medals. After the war he returned to Edinburgh and became Surgeon to the Royal Infirmary, the Lock Hospital, the Eye Infirmary, and other institutions. He also had the Volunteer decoration, having been Surgeon-Lieutenant-Colonel of the Queen's Edinburgh Rifles. He was made Surgeon to Queen Victoria in Scotland, and since 1901 Honorary Surgeon to the King. In 1881 the University made him LL.D. and in 1887 the Irish College of Surgeons made him an Honorary Fellow. In June, 1903, he was knighted. Many other honors have been showered upon him. He was a Deputy-Lieutenant, a Caballero of Spain, had been President of his College and its representative in the General Medical Council, and examiner for several qualifying bodies.

Lieutenant-Colonel J. Maitland, M.D., late of the I. M. S., has died at the age of fifty five. He graduated at Edinburgh in 1874, joined the Indian Service in 1876, was appointed to the General Hospital, Madras, of which he became in due course Senior Surgeon. In 1882 he was a professor in the Medical College and filled various appointments in the city, the college, and the hospital until in 1903 he was Principal of the college and a little later Professor of Surgery, Honorary Fellow of the University, and Senior Member of the Hospital Staff. He wrote "Elephantiasis and Allied Disorders" and various contributions on Filarial and other tropical diseases.

Dr. Sealy of Weybridge was drowned on the 24th through an accident in consequence of the Thames flooding over the bank and loosening it, so that the horse he was riding fell with him into the river.

Progress of Medical Science.

Boston Medical and Surgical Journal, January 2, 1908.

The Value of Vaccine Therapy to the General Practitioner in the Treatment of Bacterial Disease.—This paper, by C. Floyd and A. M. Worthington, gives details of eighteen cases covering a wide variety of lesions. The results of the vaccine therapy were on the whole decidedly favorable. The authors believe (1) each new method in medicine should have a thorough trial before it is rejected. (2) A non-attenuated specific vaccine, given in proper doses, is essential to success in the treatment of cases with vaccines. (3) To control the amount and frequency of the dose of a vaccine, either the opsonic index or general clinical symptoms may be the guide. (4) Localized infections of moderate duration offer the best field for treatment. (5) The vaccine treatment, when used in conjunction with medicine or surgery, may lessen suffering and deformity and frequently save life.

Personal Experience with Specific Vaccines in the Treatment of Bacterial Disease.—M. W. Richardson details his experience with infected knee joint, puerperal septicemia, lupus, pustular acne, and tuberculosis of the ankle joint. He says: (1) Bacterial inoculation cannot accomplish the impossible. It presupposes the patient has still in reserve forces to be called into action. It must be employed as early as possible. (2) Physicians, therefore, intending to make use of this method of treatment must make original cultures from septic operations. Otherwise, valuable time will be lost, as in this case, with the study of organisms invading secondarily open wounds. (3) In this connection, too, it is perhaps well to emphasize the importance of blood cultures in cases of general bacterial invasion. This procedure gives at once, if successful, the kind of organism concerned, and the material for an autogenous vaccine. Blood cultures have proved their worth, especially in typhoid fever in the early days of the disease, when the Widal reaction so often fails. In a certain German clinic, the author has heard, it is a routine procedure to make blood cultures from any patient showing an elevated temperature.

New York Medical Journal, January 4, 1907.

Potassium Iodide in Mental Diseases.—J. M. Walker presents summarized histories of several cases of cerebral syphilis, alcoholic insanity, melancholia, etc., advocating the use of potassium iodide in rebellious or critical cases in very large dosage. Such doses should be taken immediately after meals, and will be borne only when the patient is on full diet. In almost every case there has been a primary eruption situated principally on the chest and face; in most cases this occurs at from 300 to 500 grains, with also slight nausea. Both disappear on increase of dosage. The author asserts that, in his experience, in a good percentage of cases of cerebral syphilis, if treatment is begun within three months after mental impairment is first noticed, the patient will invariably regain his normal mental faculties. The eruption and nausea spoken of seem to be a primary physiological effect of potassium iodide, as nausea disappears and the skin clears up on increasing the dose to its limit or full physiological action, which is evidenced by the patient's face becoming puffy and swollen, conjunctiva injected, abundant secretion from the mucous membrane of the nares and bronchi, severe vomiting, acneform eruptions covering nearly all of the body (however, this may or may not be present); diarrhea, loss of appetite, and stupidity, which lasts from four to five days; during the period of diarrhea and emesis pulse is increased ten to fifteen beats per minute, and lasts for about forty-eight hours, after which it becomes normal. Walker admits that there may be doubt in the minds of some as to whether or not these large amounts of the remedy are being digested or are passing through the bowels without change. As proof of the former view he points to the steady gain in flesh, the marked improvement in the patient's mental condition, also the positive results in testing the urine for iodine.

Pathogenesis of Stump Hallucinations.—Some observations are offered by G. A. Gordon on this subject, his remarks being suggested by the history of a case of twenty-seven years' duration. He declares that the appearance of the hallucination upon a physical irritation of the cicatrix of the stump speaks in favor of its peripheral origin. The spontaneous development of the phenomenon when the patient is at rest and without external irritation, aggravation of symptoms after an apoplectic seizure, are all manifestations which originate primarily in the brain. The question of the pathogenesis cannot, therefore, be decided in exclusive favor of one or of the other view. Both elements play an important rôle in producing the stump hallucination. The most interesting feature of the author's case is the unusual duration of the hallucination. Cases with the stump phenomenon persisting for several years have been reported, but a twenty seven years' hallucination is very uncommon. The habit of transferring to the periphery all sorts of sensations is due to the association of visual, tactile, and motor images. Normally this habit is gradually lost; in some cases at the end of a week or a month, and in others at the end of several years. When the hallucination persists for a great many years the cerebral centers are more or less in a state of instability. Such a brain cannot be considered normal. The author's patient is alcoholic. For a number of years he used intoxicating beverages in unusually large quantities (ten to twelve whiskies and as many beers a day). This fact illustrates the validity of the view concerning the cerebral origin of stump hallucination.

The Diagnosis of Unilateral Tuberculous Nephrocystitis.—Six operative cases are reported by M. W. Ware. Of these cases all but one were in the beginning mistakenly interpreted. One was treated for a vesical

calculus, another was operated upon (nephrectomy) for a pyonephrosis grafted on a gonorrhea, which eventually demanded a difficult secondary nephrectomy. A young girl was treated for six months, in vain, for a cystitis. After nephrectomy of one kidney in the face of inflammatory changes of the other kidney (casts, pus cells by ureter catheter), a tuberculosis of this remaining kidney resulted, possibly, by an ascending process. Still another patient operated upon previously for perineal abscess which did not heal, nor give relief to his urinary symptoms (pyuria) was nephrectomized on the basis of findings with the ureter catheter. Two nephrectomies were performed in spite of pathological conditions of sister organs. No cryoscopy or other tests for renal sufficiency were applied, and no deaths resulted. The author says that to foster the stigma of tuberculosis is justified only by a rigid diagnosis by exclusion, in which all the laboratory aids possible are employed, radioscopy, cystoscopy, etc. He calls attention to the fact that the condition of "cystitis," for which the physician often refers a case to the surgeon, is really the terminal condition of some lesion higher up in the genitourinary tract. If this fact were borne in mind fewer cases of tuberculous nephrocystitis would escape recognition at a time when the lesion was unilateral and amenable to surgical measures.

Journal of the American Medical Association, January 11, 1908.

Rachitis.—T. S. Southworth deplores the lack of attention by parents and physicians to the early symptoms of rachitis. It is a disease of the well-to-do as well as of the poor, and it is an error to assume that because some of the typical symptoms may be lacking the disease is not rachitis. The beading of the ribs comes nearest to being a constant sign, and the abnormal softness of the thoracic walls may be first apparent from the sinking in of the chest walls during inspiration in some acute respiratory affection. This is a serious handicap to the child, increasing the danger of pulmonary disease and crippling the respiratory function. This softened thorax and the nervous instability of the disease are the greatest dangers and make the prophylaxis most urgent. The disease may begin before the fifth month; just how much earlier is uncertain. After that it is recognizable with increasing frequency and may be most marked during the second year. It should be the physician's duty to detect the condition in its incipiency, even in nursing infants, when he should endeavor to improve the hygienic conditions, especially by attention to the mother's diet, checking the tendency to prolonged lactation and other remedial measures. While in the earlier months prophylaxis and treatment are practically the same as that of malnutrition in general, after the fifth and sixth months certain measures begin to have a definite value. Fresh orange juice has a beneficial effect in rickets as in scurvy, and at this period or even earlier it is well to begin the use of pure cod liver oil, beginning with small doses and increasing with tolerance to half a dram three times a day. More attention should also be given to securing an adequate supply of proteid in the infant diet, and by the seventh month the administration of beef juice once daily or the white of one egg will be of assistance. In older children who have entered on their second year scraped rare meat pulp and soft boiled eggs are useful. The intelligent management of starch-containing foods is important, but it is not necessary to cut them off entirely when any considerable degree of intestinal indigestion and distention is not present. The value of cod liver oil given for long periods is incontestable. It is also one of the best mediums for the administration of phosphorus, which Southworth considers a valuable remedy to cut short the more acute symptoms and especially for the rachitic instability of the nervous system.

The Roentgen Ray Treatment of Epithelioma.—W. A. Pusey gives his experience with the *x*-ray in patients treated more than three years ago. Excluding a few cases which at the time of beginning treatment were complicated with demonstrable carcinoma of neighboring glands, the total number of epitheliomas treated is 119. He has been able to follow up the records of all but 8 of these, leaving 111 to be considered. Of this number 80 patients are either well to-day or have died from other causes without recurrence of the epithelioma. Eight are dead from other diseases, one has been well over six years, 11 are well over five years, 22 over four years, 32 over three years, and 6 were living more than three years, but have since been lost trace of. Two patients are counted as practically cured. One of these died of pneumonia fifteen months after treatment with a minute suspicious looking spot remaining unhealed. In the other there is a small non-progressing ulcer resembling an *x*-ray burn remaining. In both cases the original disease was very extensive. Seventeen patients are classed as only distinctly benefited; that is, the disease was checked and life prolonged with comfort for at least a year, except in one case in which the patient, a man over 80, died within the year. All of these cases were recurrences after surgical removal of the growth and hopeless as regards other treatment than the *x*-ray. Brief reports are given of several of these cases. In only 12 out of the whole number was the treatment counted as a failure, though in several there was some benefit afforded. Counting all the 31, however, which are classed as not entirely successful or as failures, there remain 80 cures out of the 111, or 72 per cent., a showing which Pusey thinks will equal that afforded by any other method of treatment.

Adenomyoma of the Uterus.—T. S. Cullen has found these growths in over 5 per cent. of between 1,300 and 1,400 cases of myoma. Their pathological anatomy is described in detail; there is first a diffuse myomatous thickening of the inner muscular walls accompanied by a down-growth of the normal mucosa into this diffuse growth. Portions of this adenomyoma may become subperitoneal or intraligamentary and may form a large cystic adenomyoma. Portions of the diffuse growth may also project into the uterine cavity, forming submucous adenomyomata. The growth may also occur exceptionally in the cervix with like extension of the uterine glandular structure. No proofs of any causal relation between the ovaries and tubes and the development of adenomyoma could be found. The disease is most common between the ages of thirty and sixty, is found in both single and married women, and does not seem to militate in any way against normal pregnancy. The diagnosis is difficult and impossible in subperitoneal and subligamentary cases until the abdomen is opened. If a diagnosis can be made, abdominal hysterectomy is indicated. While Cullen considers these growths themselves to be benign, the coexistence with them of a squamous carcinoma is not rare, and they may themselves develop into adenocarcinoma. In the vast majority of cases the gland elements are derivatives from the uterine mucosa, though the continuity may sometimes not be traceable. The author's summary is given substantially as follows: In the examination of fifty uncomplicated diffuse adenomyomata of the uterus the mucous membrane origin of the glands could be traced in every case. In six additional cases with complicating squamous-cell carcinoma, the continuity was established in five. In the two remaining cases of adenomyoma of the body the continuity was destroyed by adenocarcinoma. In the remaining fifteen cases of subperitoneal or submucous adenomyomata one would naturally not expect to trace the relationship; nevertheless, in one case the mucosa literally flowed into the myoma. Thus, taking all kinds together, Cullen was able in 56 out of 73 cases to trace the origin of the gland element to the uterine mucosa. All adenomyomata of the uterus in which the gland elements are similar to those of the uterine mucosa, and surrounded by stroma characteristic of that surrounding the normal uterine glands, owe their glandular origin to the uterine mucosa or to Müller's duct, no matter whether they be interstitial, subperitoneal or intraligamentary, solid or cystic.

The Opsonic Index in Orthopedic Surgery.—C. Ogilvy and T. H. Coffin give an account of their work undertaken to determine: 1. The opsonic index in cases of tuberculous bone and joint affections; 2, the effect of tuberculin on the opsonic index in these tuberculous cases; 3, the relation between the opsonic index and the general and local conditions; 4, to compare the opsonic indices of patients living under the best hygienic conditions, but without the use of tuberculin. Several cases are briefly reported and the chief details of importance in a number of others are given. All were cases of tuberculous disease of the hip, knee, or spine. The authors feel warranted in offering the following deductions from the observations thus far: 1, Tuberculin in small doses and at proper intervals is of undoubted value in the treatment of selected cases of tuberculous bone and joint disease. 2. The rise of the opsonic index is accompanied by an improvement in the general and local conditions, provided there is no secondary infection. 3. The opsonic index will be of value in determining the advisability of discontinuing mechanical treatment. 4. The opsonic index is of value in determining the prognosis of tuberculous bone and joint disease. 5. When there are discharging sinuses and mixed infections the opsonic index may be raised by the use of tuberculin without corresponding improvement in the general or local conditions (specificity).

The Lancet, December 28, 1907.

Appendicostomy in Chronic Dysentery.—J. A. Pottinger states that the most striking result of this opera-

tion is the facility with which the irrigation of the large bowel can be effected. It has also been employed in chronic constipation for the administration of suitable medicinal remedies having a local action, while its use has been suggested in complicated cases of enteric fever and in cases requiring gastrostomy as a substitute for the graver operation. It is in dysentery and more particularly the chronic variety, that the operation seems in some cases to give very gratifying results. The author records the history of a man of twenty-seven years who had been ill for six weeks, having as many as twenty daily passages of mucus and blood. The patient did admirably and a perfect cure resulted. The author calls attention to a few technical points as illustrated by the progress of this particular case. The catheter was at first removed between each occasion of irrigation, but it was found that even in twenty-four hours the wound closed so, owing to the growth of granulations, that it was somewhat difficult to find the opening, and latterly a soft rubber instrument was used and was left in the opening, being removed each day, of course, to be cleaned. Care was taken never to have a big "head" of fluid and no attempt was ever made to *dilate* the bowel, free passage through the rectal tube obviating this, which in an extensively ulcerated condition of the gut would have been a true danger.

Diarrhea, Erythema, and Asthma Apparently Due to Nasal Disease.—The patient of J. W. Stenhouse was a woman of thirty-nine years with a diarrhea which had lasted some six months. Later asthmatic symptoms came on and still later erythema urticaria. It was noted that the asthmatic attacks were accompanied with a degree of nasal obstruction. Examination of the nose suggested the advisability of a partial turbinectomy and rectifying of a malposition of the septum. As a result of this treatment the patency of the nasal passages was reestablished and the patient has since had complete immunity from all her symptoms, asthma, diarrhea, erythema, and tachycardia. The author does not suggest that this is absolute proof that the intranasal condition was the starting point of the various reflexes in an unstable nervous system, but merely states the facts as they occurred.

Infantile Gangrene of the Cornea in which the Treponema Pallidum Was Found.—A series of four cases is reported by S. Stephenson. This corneal condition known as keratomalacia is characterized first by athrepsia, and, secondly, by a sloughing condition of one or both corneæ, associated with but slight symptoms of local reaction, such as redness, reflex blepharospasm, or swelling of the eyelids. Curious, dry, frothy-looking patches of xerosis (first described by von Graefe) may sometimes be found in the ocular conjunctiva. They are not essential to the diagnosis. The necrosis of the cornea, contrary to what might be expected, is not due to any particular microorganism. Practically any pyogenic microbe, other conditions being favorable, may cause keratomalacia. In the author's cases he found *Staphylococcus albus, aureus,* and *citreus,* as well as pneumococcus, *Bacillus coli,* and, of course, the xerosis bacillus, or, as it is better designated, the *Bacillus communis conjunctivæ* (A. Lawson). Keratomalacia often leads to destruction of the cornea and, if the cause in the shape of some general illness cannot be grappled with, to the death of the patient, usually from bronchopneumonia. In all the four cases of the author the *Spirochæta pallida,* or an organism not to be distinguished from it, morphologically, was demonstrated in smears from the affected cornea when stained by the Giemsa and the Proca-Vasilescu method.

British Medical Journal, December 28, 1907.

Malignant Endocarditis Lasting Over Six Months Without Bruit.—In the history of a case reported by R. Capes an interesting point is that, although the illness and the pyrexia lasted seven months, at no time was a bruit ever heard, though the patient was seen by five medical men, all of whom were looking out for signs of heart disease. The rapid wasting at the end, with the enlargement of the liver and spleen, and loss of consciousness, made the theory of growth seem likely, though the continued rise of temperature for so many months was against it. Hence although the petechiæ, the pyrexia, and the slightly increased heart rate all pointed to a possible fungating endocarditis, a positive diagnosis was not arrived at. Even towards the end, as the liver became quite as much enlarged in proportion as the spleen, the diagnosis still remained doubtful. Cases not infrequently occur in which for a long time there is no bruit, or only a very doubtful one; but it is very exceptional for a case of such prolonged duration to remain without a bruit throughout. The patient was a man of sixty-four years, whose illness began with an influenza attack. The autopsy revealed fungating endocarditis. There were three small flattened patches of vegetations on the inner margin of the mitral valve, firm to the touch and not friable. Their surfaces were fairly smooth and uniform. These surfaces allowed the valves to come together so that there was no incompetency; hence presumably the absence of the murmur. The masses lacked the usual verrucose appearance so often present in such cases, and which invariably interfere with the competence of the valves. The firm, flat, smooth, non-friable character of the vegetations indicate why there were no physical signs of valve lesion. There were three small hemorrhages in the cerebral cortex, two on the right side—namely, one in the temporo-sphenoidal lobe and one in the fissure of Rolando; one on the left side in the second frontal lobe. There were infarcts in the spleen and kidneys, and the liver was enlarged. The lungs were engorged.

The Automatic Rhythm of the Heart.—A. M. Gossage comments on the prolonged controversy during the last twenty-five years as to the origin of the automatic power of the heart to beat rhythmically and reviews the various stages of the discussion. He notes that the arguments adduced hitherto are on the whole rather in favor of the venous origin of the stimulus, but declares that they are not incompatible with a muscular source. It has been disproved that every cardiac muscle fiber is capable of supplying its own stimulus and beating independently. It is certain, however, that the muscular fibers possess the properties of contractility, excitability, conductivity, and tonicity, and it is probable that these are experienced during the normal beat of the heart without the intervention of the nervous tissue. It is also certain that all the muscle fibers are not capable of building up a stimulus for themselves, but there is evidence to show that certain fibers of peculiar structure possess this property. While certain facts seem to find their readiest explanation in the neurogenic theory, especially the response of the quiescent heart to the stimulation of the accelerator nerve, there are others pointing as strongly to the hypothesis that the heart beat is purely muscular; and in the face of Engelmann's direct observations on the great veins in frogs and the occurrence of pulsation in the embryo heart before development of nervous elements, it seems to me that the complete myogenic theory has the more weighty evidence in its favor, and should be accepted until stronger arguments are brought against it. The conception that the rhythmic beat is purely muscular in its origin does not preclude the possibility of the beat being influenced by outside nervous impulses; this would give a sufficient explanation of the large nerve supply to the heart. Attributing the rhythmic power of contraction to the muscle is, of course, only a very partial explanation of the cardiac beat, the cause of which lies deeper in physicochemical changes in the cells.

Tuberculous Chlorosis.—A. James states that when we meet with a case which presents in a more or less marked degree all the ordinary appearances of chlorosis, and which yet on examination of the blood reveals the number of red corpuscles and the percentage of hemoglobin to be practically normal, we are very likely to find in it a history of past or present tuberculous disease. This condition, often occurring in young women, is one which long ago Trousseau recognized and called false chlorosis or tuberculous anemia; and although in recent times, when blood examination has become more of a routine procedure, the coexistence in tuberculous disease of an anemic appearance with a practically normal blood count is quite recognized, it seems that in cases apparently of chlorosis this possible association of tuberculous disease often passes for long unrecognized. Inasmuch as the recognition of such cases is important from the points of view alike of diagnosis, etiology, pathology, and treatment, the histories of three cases of this category are given in detail. In a general way such cases, though more tedious than those of ordinary chlorosis, recover fairly well. But although their general condition may improve, the blood count remains practically the same. It is believed that such cases present in reality an oligemia, that is, a diminution in the total amount of the blood. Trousseau believed that iron should be avoided and placed his reliance on arsenic and general hydrotherapy. The author believes that the condition is one which occurs in individuals who, as the result of hereditary or acquired causes, have given indications that they possess low resistance power to the tubercle bacillus. In what way and to what extent this blood effect may be salutary as regards tuberculous lung disease, we can only conjecture. The author's idea is that it may be by inducing an air hunger, and so stimulating lung function and nutrition. Anyhow, when we reflect that the quality of the blood is quite good, we can under-

stand that treatment to improve the health generally rather than the blood specially is what is required.

The Mental Origin of Neurasthenia and Its Bearing on Treatment.—D. Drummond points out the fact that in neurasthenia the physical symptoms are generally without any physical basis. The mental history of both the patient and his family are of great importance. It may be difficult to have a definite family history, but with care this can usually be made out and not infrequently it will include cases of insanity. Clinically considered, this is of much importance in establishing the mental origin of the neurasthenic disorder; in practice what it points to is the fact that serious dangers particularly threaten persons who inherit a nervous temperament, for whom, therefore, special safeguards in home surroundings and personal habits ought to be observed, just as those who inherit a tendency to tuberculous mischief must observe careful precautions in their surroundings and manner of life if they are to escape harm. Drummond believes that overwork, mental strain in business or other ways, the grief of bereavement, or some alarming shock, do not in themselves produce neurasthenia and cannot be said to be its cause, though by lowering health and weakening mental control they may contribute to the development of the more serious disturbance. On the other hand, he emphasizes the cramping and damaging effect on the mind of uncontrolled and bad habits of thought in early life, partly because of its testimony to the mental origin of neurasthenia, and also on account of a growing conviction that to such habits may be ascribed a great deal of the depression and mental discomfort from which nearly every one suffers at times. Treatment calls for a combination of insight, sympathy, and firmness that all do not equally possess. The personal factor of the physician cannot be overlooked or minimized. There must be an honest and straightforward statement to the patient dealing with the facts of the case—a statement that enters fully ino its pathology and touches lightly upon the symptoms: a statement that, by its very firmness, disinterestedness, and kindliness, wins the confidence of the patient, and encourages him to think better of himself, and to make a real effort to rise above his trouble and ignore himself. The power to help and encourage our nervous invalids undoubtedly increases with experience and practice; and the sooner we begin to talk rationally to them the sooner will we acquire the art of curing them.

Berliner klinische Wochenschrift, December 23, 1907.

Neuralgia of the Rectum.—Albu says that this is a purely nervous disease, having as its chief or only symptom pain in the rectum, anus, and adjoining parts. The pain radiates into the gluteal regions, toward the sacrum and perineum, and even, as in two of the author's cases, into the thighs. The pain is described as boring, burning, or lightning-like; is sometimes extremely severe, comes on in sudden seizures, and lasts from a few minutes to several hours. Sometimes the sufferer is rendered incapable of work by day and of sleep at night. The patients always suffer from neurasthenia, due to mental overexertion, psychical stress, irregular living, the misuse of alcohol, or tobacco, etc. Of Albu's five patients four were men, while Gant says that women are more often affected than men. Albu was not able to determine any cause for the onset of the disease and found that it had no relation to constipation. The diagnosis should be made only by exclusion and every other possibility should first be thought of. As examples of possible sources of error, he describes the cases of two patients whose symptoms for a time simulated rectal neuralgia, but one of whom suffered from carcinoma of the prostate and the other from tabes. The treatment includes anodynes by mouth, rectum, and subcutaneously, avoiding opium and its derivatives, belladonna in large doses proving very useful. Other measures are hot sitz baths, douches of hot water and steam, hot compresses, moist applications, etc. A most effective procedure is the systematic introduction of thick bougies, which apparently act by distending the diseased nerves. Regulation of the bowels should, of course, not be neglected.

The Technique and Significance of Wasserman's Syphilis Reaction.—Meier describes the latest modifications in technique that are now used in Wasserman's laboratory and also gives the results of the application of the method in a considerable number of clinical cases. Three hundred and fourteen serums, twenty-nine cerebrospinal fluids, one placenta, and one hydrocele fluid were examined. Of the 181 patients known to be syphilitic 81.7 per cent. gave a positive reaction, 2.7 per cent. a doubtful reaction, and 15.6 per cent. a negative reaction. In 21 cases in which syphilis could be excluded the result was always negative. The author concludes that the test is specific for syphilis and that it is sufficiently reliable to afford a useful addition to our diagnostic methods, but that its complicated nature demands a skillful and experienced worker for its performance.

Münchener medizinische Wochenschrift, December 24, 1907.

Functional Tests of the Gastric Function.—Tottman has made very complete investigations of the gastric function in 60 cases of various sorts. In addition to the usual analysis of the test meal, Mett's pepsin method was used, Sahli's desmoid pills were given, and Schmidt's test diet was administered in order to determine the ability of the stomach to digest connective tissue. As the result of these comparative investigations Tottman states that the use of the stomach tube is the most unpleasant for the patient, but in cases of pronounced disease affords very reliable information. In instances of milder disorder it is less to be depended on and may even lead astray, since its introduction may of itself interfere with gastric efficiency. Schmidt's diet forms a most useful method and is little if at all liable to error. It is not adapted for repeated application, since the patients usually are not willing to resort to it a second time, and it is also unsuitable when only fluid food can be taken. Sahli's method can be used in all cases and is the most agreeable for the patient. Careful preparation of the pills from material of approved quality is an essential, and two pills should always be given at an interval of about five minutes. Under these conditions a negative result is more dependable than in the case of the test meal and is almost as reliable as with the Schmidt diet. Positive results must be accepted with more caution. It is very well adapted for use as a method for rapid orientation and for repeated application in watching the patient's progress.

Antitoxin and Albumin.—Much reports interesting experiments on the composition of antitoxins. Tetanus antitoxin was injected into women just before or some days after delivery and could be identified in the milk and in the serum of the infants. Ordinarily, however, when serum is given by mouth it does not reach the bloodstream unaltered. By means of the precipitin method and the fixation of the complement it was then shown that the mother's milk did not contain horse serum. The milk when injected into a nursing rabbit caused antitoxin to appear in the milk of this animal, but neither horse nor human serum could be detected in the milk. Three possibilities may be considered in connection with these phenomena: 1. The basis of the antitoxin remains horse serum, but can no longer be identified as such. 2. The horse antitoxin is converted into human antitoxin and then into rabbit antitoxin. 3. The antitoxin is not an albumin at all, and the mammary gland can effect what is not possible in the test tube, viz., the separation of the antitoxic function from the albuminous base. This assumption is the most daring, but also the most probable.

Twenty-five Conservative Cesarean Operations Without Maternal Mortality.—Eliseo Canton describes a series of twenty-five conservative cesarean sections done without a single maternal death, and gives his conclusions from this experience. The conservative cesarean section is no longer a fearful operation, but, thanks to antisepsis, every such operation lessens death from labor. In contracted pelves whose diameter is less than seven centimeters and a half, with a livng infant of normal development, the cesarean section is absolutely indicated. In contractions with diameter of more than seven and a half centimeters, with a living normally developed child, cesarean section should be done whenever the disproportion between the diameters of the head and the pelvis does not permit of the engagement of the head after several hours of strong contractions. In the same conditions with a diameter more than seven and a half centimeters, the choice between the cesarean section and symphyseotomy should be made for the first whenever the life of the mother is to not be preferred to that of the child. Under the same conditions the choice should be made between subcutaneous pubiotomy and the cesarean section according as the life of the infant or the mother is most important, since section is most beneficial for the child, and pubiotomy for the mother. In case of fever or infection pubiotomy is to be preferred. In contractions of more than seven and a half centimeters section is to be preferred to version in the interests of both mother and child. Between premature labor and hysterectomy we should choose the first on behalf of the child. In severe eclampsia forced labor is to be preferred in the interests of the child and mother.—*Annales de Gynécologie et d'Obstetrique.*

Book Reviews.

Insanity and Allied Neuroses. A Practical and Clinical Manual. By George H. Savage, M.D., F.R.C.P.; Late Physician and Superintendent of Bethlehem Royal Hospital; Lecturer on Mental Diseases at Guy's Hospital, and Co-editor of *The Journal of Mental Science*. With the Assistance of Edwin Goodall, M.D. (Lond.), B.S., F.R.C.P.; Medical Superintendent of the Cardiff City Hospital for Mental Diseases; Late Medical Superintendent Joint Counties Asylum, Carmarthen, and Co-editor of *The Journal of Mental Science*. With Six Colored Plates and Forty-five Illustrations in the Text. New and Enlarged Edition. Chicago: W. T. Keener & Co., 1907.

The general practitioner, in this country at least, has perhaps made greater use of Dr. Savage's manual than the psychiater, and this may continue to be the case. In this preface to the first edition the author states: "In this book I shall describe insanity and trace its life history. I shall explain the legal relationship of the insane, and make plain the duties of the physician who has to be responsible for their safety and welfare." In treating of idiocy, epilepsy, and chronic mental disorders he acknowledges drawing on the experience of others. In the present (fourth) edition the preface contains the remark: "I believe that all that is essential for the student of mental pathology, and for the general practitioner who needs aid and direction, will be found in this amended volume." The author conserves his former "provisional" classification, which he considers "more useful than elaborate new plans which would entail labor to the student to master, and which would in the end have to be thrown aside." Descriptions in such a small volume are necessarily brief. Chapters and appendices on legal relationships and hospitals, as long as the book is apparently for American readers, might preferably have related to America rather than to Great Britain.

A Manual of Hygiene and Sanitation. By Seneca Egbert, A.M., M.D., Professor of Hygiene and Dean of the Medico-Chirurgical College of Philadelphia; Member of the Academy of Natural Sciences of Philadelphia; Member of the American Medical Association, etc., etc. Fourth Edition, Enlarged and Thoroughly Revised. Illustrated with Ninety-three Engravings. Philadelphia and New York: Lea Brothers & Company, 1907

The present has come to be recognized as one of the standard works on hygiene and sanitary science and its appearance in another new edition bears evidence of the appreciation of many readers. The author states that to bring the work fully up to date every sentence has been reviewed and many changes have been made, besides the addition of about twenty pages of new matter That the revision has been a thorough one is shown by the presence of sections on the opsonins, on the permanganate-formaldehyde method of disinfection, on the construction of septic tanks for sewage disposal for private dwellings, etc. One of the few criticisms that suggests itself to the reviewer is that the illustration on pages 48 and 119, respectively, seems hardly important enough to require another appearance later on in the book. Figure 33 is referred to on page 188 when it is Fig. 36 that is meant. It is a pleasure to call attention to this most satisfactory book on a highly important subject.

Diseases of the Stomach. By Dr. I. Boas, Specialist in Gastroenteric Diseases in Berlin. The sole authorized English-American Edition from the latest German Edition, by Albert Bernheim, M.D. (Freiburg, Germany), Philadelphia; Assistant to the Late Dr. D. D Stewart at the Polyclinic Hospital and Post-Graduate School, as Instructor in the Department of Diseases of the Stomach and Intestines; Privileged Physician to the Jewish Hospital of Philadelphia; Examining Physician to the Free Hospital for Poor Consumptives, Philadelphia —White Haven; Consulting Physician to the Nazarene Home for the Aged; ex-President of the Northern Medical Association of Philadelphia Illustrated with Five Full page Plates and Sixty-five Engravings in the Text. Philadelphia: F. A. Davis Company, 1907.

The work just issued compares very favorably with its predecessor which dealt only with the diseases of the intestines. Hitherto there has been no authorized translation into English of Dr. Boas's views, *in toto*, on diseases of the stomach, and a well deserved reception may confidently be expected to meet the present edition. The author has made his text perfectly clear, readable, and interesting. The many conflicting views which he considers irrelevant are calmly ignored, leaving a virile presentation of his personal views which, when read, are also remembered. Rarely does he hesitate, but rather speaks with an authority that begets conviction. Throughout, the large personal experience of the author shows as plainly as it would in a didactic lecture, and we feel that it especially fits the needs of the general practitioner.

In the first two chapters, the topography, histology, physiology, and chemistry of the stomach are dealt with concisely and in a practical manner. The author then divides his work into two large parts, the general and the special. The first deals with an excellent system of history taking and the examination of the patient, and about one hundred pages relating to the examination of the gastric contents. He concludes the first part with urine and blood analysis, and general methods of treatment, such as diet, balneotherapy, physical therapeutics, and medicinal agents. The second part is more like the usual text-book arrangement of the subject and treats each disorder separately. The writer is fair and rational in his opinions, practical in his therapeutics, and in diagnosis has the necessary breadth to make a good clinical teacher and a helpful guide.

Gynecology and Abdominal Surgery. Edited by Howard A. Kelly, M.D., F.R.C.S. (Hon., Edin.), Professor of Gynecologic Surgery at the Johns Hopkins University; Gynecologist to the Johns Hopkins Hospital, Baltimore; and Charles P. Noble, M.D., Clinical Professor of Gynecology at the Woman's Medical College, Philadelphia; Surgeon-in-Chief, Kensington Hospital for Women, Philadelphia. Illustrated by Hermann Becker, Max Brodel, and Others. Volume I. Philadelphia and London: W. B. Saunders Company, 1907.

Among the novel features of this latest work on gynecology may be mentioned the recognition of the close relationship existing between gynecology and general surgery, the inclusion of certain obstetrical subjects which are closely allied to gynecology, the presence of a lengthy chapter on medical gynecology, the absence of matter of an elementary kind which is found in every text-book, the insertion of much interesting material on the historical development of gynecology and abdominal surgery, and chapters on special subjects such as operations before puberty. In the present volume H. A. Kelly contributes the chapters on Gynecologic Technique; Vesical Fistulæ; Vaginal Drainage for Pelvic Abscesses; Conservative Operations on the Ovaries and Tubes, and (in conjunction with E. Hurdon) Operations before Puberty. The latter also supplies the chapter on the Pathology of the Reproductive Organs. C. P. Noble is responsible for the chapters on Plastic Operations on the Perineum, Vagina and Cervix; Curetage of the Uterus and Inversion of the Uterus; the Preparatory Treatment of Celiotomy Cases; After-Treatment of Celiotomy Cases; the Celiotomy Incision; Operations for Retrodisplacement and Prolapse of the Uterus; Abdominal Hysterectomy and Myomectomy; Vaginal Myomectomy, and (with B. M. Anspach) on Medical Gynecology. Bacteriology is handled by W. W. Ford. A. M. Fullerton writes on Non-plastic Operations of the Vulva and Vagina. G. M. Edebohls has a short chapter on Combined Gynecologic Operations. G. L. Hunner is responsible for the chapter on Diseases of the Bladder and Urethra. Ovariotomy is treated by A. J. C. Skene. H. T. Byford is responsible for the chapter on Vaginal Section for Diseased Ovaries and Tubes. J. C. Webster writes on Removal of the Uterine Appendages Abdominal Hysterectomy for Inflammation of the Uterine Appendage is contributed by J. M. Baldy. Radical Abdominal Hysterectomy for Cancer of the Uterus is from the pen of J. G. Clark. The Byrne Method of Treatment of Cancer of the Uterus is by X. O. Werder, and F. Henrotin supplies the chapter on Vaginal Hysterectomy. It will thus be seen that the editors have drawn up an attractive bill of fare; and on sampling many of the chapters and reading some of them we find that the expectations aroused by the preface and contents are fully realized. The two longest chapters in the book, and in some respects the most important, are those on Medical Gynecology and on the Pathology of the Reproductive Organs. The former of these will prove of much value to the general practitioner, who will find in this one chapter much of the information which he requires on gynecology. The chapter on Ovariotomy contains much that is found in the same words in Skene's "Diseases of Women," published twenty years ago! The reader can choose for himself between the abdominal and vaginal routes for the performance of various operations; the claims for each method are well presented by eloquent advocates. The book is well printed and illustrated. For the surgeon, the gynecologist, and the general practitioner it will prove valuable.

Society Reports.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held December 23, 1907.

THE PRESIDENT, DR. WALTER LESTER CARR, IN THE CHAIR.

Memorial Address.—Seneca D. Powell, M.D. By Dr. EDWARD D. FISCHER.

Treatment of Hyperphonia (Stuttering and Stammering) by the General Practitioner.—Dr. EDWARD W. SCRIPTURE read this paper. He said that stuttering and stammering were terms loosely applied to one disease, which might be defined by its fundamental symptom, namely, excessive innervation of the vocal cords. The disease might, in fact, be properly termed "superenergetic phonation," or "hyperphonia." (See MEDICAL RECORD, May 11, 1907, page 771.) This disease had no connection with another disease of speech which arose from insufficient and mistaken coordination of the speech muscles, due to defects in the vocal organs, in the nervous control, and in the ear. This form of speech defect might be properly termed "subenergetic phonation," or "hypophonia." The symptoms of superenergetic phonation might be classed as follows: 1. Cramps and hypertonicity of the breathing muscles. He had had several cases in which the cramps had lasted twenty to thirty seconds. 2. Cramps and hypertonicity of the laryngeal muscles. These sometimes went along with the breath cramps and shut the larynx up tight so that no tone could be produced. About nine-tenths of stutterers spoke in a monotone; this was presumably due to the fact that it was easier to fix a group of tight muscles for one position than to keep them in easy action. 3. Cramps and hypertonicity of the muscles of pronunciation. The patients who forcibly contracted these muscles for a moment or more were often called "convulsive stammerers." Those who had a series of cramps whereby they repeated a sound were termed "stutterers," or "reduplication stutterers." There was no essential difference between the two classes. 4. Accessory cramps, contortions, and tics. He said the specific term for the disease would thus be "hyperphonia," and the three groups of symptoms would be called "respiratory, laryngeal, and articulatory cramps." The facial and bodily contortions might be termed "accessory spasms and tics." He believed the disease to be a pure psychomotor neurosis; it was a habit over which the patient had no control. Among the exciting causes were found irritation in the breathing organs, as from adenoids, imitation of other stutterers, injuries to the breathing organs, fright, etc. The general therapeutic indications were naturally treatment of any nose or throat trouble that might be present, building up the general health, etc. Every case of hyperphonia required special therapeutic procedures. In most instances he began at once to teach the person to speak melodiously, using little verses, and sliding the voice somewhat excessively. Then the individual was taught to speak and converse with melody. This "melody cure" was as simple as it was effective, and Dr. Scripture stumbled on it quite by chance while trying the various other cures. Fully one-half of the patients would absolutely cease to stutter as soon as they had learned to speak melodiously. The reason why this cure was so effective was that the stuttering habit was associated with one definite manner of speaking. It was not carried over to a manner of expression that the patient felt to be utterly different. A stutterer never stuttered when he sang, because singing was to him something quite different. Expressiveness was developed. Most hyperphonics were stiff and awkward in their manner of expressing themselves, in their posture, in their gestures, etc., and for these defects it was well to exercise them in talking with gestures, in declaring emotional pieces, etc. They should have distraction from the compulsive idea. The patient might be taught to beat time in a vigorous and snappy way, for instance. These procedures would produce a permanent cure in three-quarters of the stutterers and stammerers, if practice was given at first as often as possible and then at steadily increasing intervals. Dr. Scripture then presented some of his patients.

Dr. CHARLES L. DANA expressed the interest that all felt in the demonstration by Dr. Scripture. It was generally agreed that stammering was a form of mental tic. His own experience showed that a certain percentage of stutterers got well, outgrowing the trouble without any particular difficulty; then again there was a certain proportion that never got well. A good deal of the success depended upon the faithfulness of both the teacher and the student. A good many boys started well in the treatment, but unless they kept it up relapses would occur.

Dr. L. PIERCE CLARK said that he believed Dr. Scripture's studies were sound and in the right direction concerning the nature and cause of stammering. The disorder was no doubt to be classed with the minor psychomotor neuroses. Its real pathogenesis was a disorder in coordination of mental associations. A block in the outlet of the flow of vocalization in speech resulted in a spread of the cramp defect into other adjacent and closely related motor centers, such as spasms of the face and finally in the upper and lower extremities. Thus the manner of spread of the cramp was an exquisite illustration of the well-known diffusion law of motor discharge in cortical centers, vulgarly represented as the ever-widening circles or waves caused by throwing a stone in the water. It seemed to him the most practical issue to be drawn from Dr. Scripture's study was the importance of the ounce of prevention idea. These speech disorders were so much more readily overcome before the cramp habit was old and fixed. Taken early the cure habit ought to have an equal chance with the cramp habit. Mental analysis for the initial cause of the cramp ought to go hand in hand with the suppression and substitution treatment shown by Dr. Scripture. He was struck with the fact that nearly all the stammerers were usually of emotional and sensitive temperaments. No doubt faulty mental hygiene in the home and school associations produced or increased the stammering defect in such, a remedy for which was quite obvious to all who dealt much with neurotic children.

Dr. L. E. LA FÉTRA said he wished to bear testimony to the success obtained by Dr. Scripture in the cases referred to him at the Vanderbilt Clinic. It was necessary that these patients should be taught to breathe properly. He thought that all must admire the ingenuity of the mental therapeutics employed in the treatment of these cases; he managed and redistributed the nerve forces and so accomplished his results. An interesting thing was giving the child another voice.

Dr. GRAEME M. HAMMOND said he did not believe that a severe stammerer ever got over this trouble as long as he was sensitive; embarrassment made him stammer more. The cure of a severe stammerer was at most a matter of time. No stammerer stammered when alone. He should learn to speak when alone. Timidity was a most potent factor in keeping up stammering.

Dr. Scripture said that the moment the patient, even in severe cases, found another voice, he gained confidence and was then all right.

The Treatment of Trifacial Neuralgia: General Medical Treatment.—CHARLES L. DANA spoke on this subject. Trifacial neuralgia, he said, was a name given to a group of symptoms characterized by pain along the course of the trigeminal nerve. It might be caused by toxins and diseases of all sorts. No single measure of therapeutics availed against it. There was a subgroup

of the disease known as tic douloureux, a definite, easily recognized clinical condition. Tic douloureux was not one thing Symptomatic tic douloureux might be caused by a growth or tumor, or exostosis, or other organic conditions. Symptomatic tic douloureux he said he would not consider. This disease was one of early life, before the age of forty, and was severe and chronic in its manifestations. He called attention to the association of these tics with migraine. In typical cases these attacks fused into one and left the patient with a typical trifacial neuralgia. He called this form of tic migrainous tic. This form occurring in the younger class of people was one which he did not believe should be operated upon. The more they were operated on the worse were they made. The operative treatment of tic douloureux might be very effective in the degenerative form of the disease, but should be applied cautiously in early life. True tic douloureux was a degenerative neurosis affecting the trigeminal nerve and occurred rarely before the age of forty. The pathology of the disease he said he did not know. It seemed to him to be a degenerative condition affecting the peripheral nerves. It seemed associated with vascular conditions so much that it seemed as much a vascular as a nervous disease. As was first demonstrated many years ago, the blood supply to the nerve in these cases was very poor. Degenerative tic douloureux was a disease about which one must bear in mind one point, *i.e.* the tendency to get well spontaneously. There was another peculiarity—its great tendency to remissions. The attacks at first might last for weeks and recur in six months; or they might recur two or three times a year. The remissions and disappearances of the pain for several months a year were a characteristic feature of the disease. Because of this fact he had seen many cases supposed to be cured by all sorts of agents, such as Christian Science, osteopathy, etc. He had also seen a case supposed to be cured by washing out the antrum, when there was nothing wrong with the antrum. So far as the medical treatment went, his therapeutics were pretty well formulated. If he got hold of a case of tic douloureux not over two or three years in duration, he gave the rest cure and doses of strychnine; in more than one-half the cases the patient would have the remissions and in one or two years there would be no return. If the disease had lasted five or six years the rest cure had some but doubtful value; such cases should be sent to the surgeon. He had not had much experience with the alcohol treatment. As to the surgical treatment, he said he was satisfied that the operation as performed by Dr. Robert Abbé was an effective and satisfactory one.

Schlösser's Alcohol Injections for Facial Neuralgia.—Dr. Otto Kiliani read this paper. (See page 90.)

Electro-Anesthesia: Introduction to the Subject and Its Surgical Possibilities.—Dr. James E. King (by invitation) read this paper. He said that many of the great advances in surgery had only been possible through the agency of general anesthesia; advances in surgery had been in direct ratio to the improvements made and perfection obtained in safely abolishing sensibility to pain. All the agents at present, however, at their command for this purpose were more or less lethal poisons to the organism. It could now be safely said that there would be no further improvement in anesthesia with the agents at their command at present. Anesthesia as they had it to-day was not an unmixed blessing, and even the most sanguine optimist must admit that there was still much to be desired, and every effort to discover new agents or methods for anesthesia should receive hearty encouragement from the profession. Some three years ago, in conversation with Dr. E. W. Scripture, he detailed to Dr. L. Pierce Clark and himself some experiments undertaken by him some years before in the production of local anesthesia by the sinusoidal current. They then decided to consider ways and means for undertaking further experimentation. Before they had completed their arrangements, however, the article by Stephen Le Duc appeared describing the use of a special current by which he obtained local and general anesthesia. Then they decided to abandon their original plan and to first experiment with the Le Duc current. He touched only upon the more salient and significant features of their work. Dogs were used for general anesthesia. After describing the peculiar current used, he said the points selected for the application were over the cerebrum and on the back over the kidneys in order that the current might pass through the brain and spinal cord. The shaving and cleansing must be carefully done, for any hair offered a considerable resistance to the passage of the current and interfered with the success of the experiment. The head electrode was attached to the negative pole and the back to the positive pole. Until the resistance of the skin was overcome there was no effect. As the current began to be felt the animal looked about in a dazed manner. From this point the increase in voltage should be very gradual. The dog quickly passed into a stage of excitement which was quite analogous to the same stage seen in chloroform and ether narcosis. At this stage the current was increased more rapidly and the animal lapsed into unconsciousness. A slight further increase in the current would secure relaxation and abolition of all movements. The dog could then be placed in any position and operations performed. After the current was shut off the awakening was immediate and the dog rose to his feet at first a litle confused, but soon acted the same as before his anesthesia. He had kept dogs under the current from a few minutes to two hours and found the animal recovered as quickly after the longer period as the shorter. The circulation did not seem to be much affected, except for a slight rise of blood pressure. In some of the animals the respiration was very much embarrassed throughout the anesthesia and this difficulty had been their most difficult problem. When death occurred it was from respiratory failure, but it was possible in many cases to restore the animal by artificial respiration, as the heart continued to beat long after the breathing had ceased. The same current had been used for local anesthesia, but their experience would seem to indicate that at its present imperfect state it might have a limited range of practical usefulness. The only record of the use of this current in producing general anesthesia in man was the testimony of Le Duc himself, who twice submitted himself to it. He described his experience as not an unpleasant one, except for the mental distress arising from the realization of the gradual loss of his faculties. With this came a feeling of helplessness and inability to make voluntary movement or speak. He characterized it as a nightmare. The fear of the current prevented the experimenters from pushing the voltage to a point where loss of consciousness and anesthesia were complete. The length of time he was under its influence was twenty minutes. Upon cessation of the current the return to normal was immediate. They believed that the problem of anesthesia would one day be solved in this way.

Demonstration of Le Duc's Apparatus.—Prof. F. L. Tufts of Columbia University (by invitation) demonstrated and explained this apparatus.

Value of the Le Duc Current in Neuralgia.—Dr. L. Pierce Clarke considered this phase of the subject. He said that more extended experiments were necessary to determine the final value of the Le Duc current in neuralgia. The majority of thir electric currents were nerve stimulants, such as faradism and galvanism, but few currents lent themselves readily as nerve sedatives. He believed the Le Duc current was one of the best of this latter class. Until very recently it was generally held that the brain was not directly excitable by the electric cur-

rent. Until 1870 all investigators like Magendie, Flourens, Louget, Weber, and others believed in the non-excitability of the brain. During the seventies, although a host of new facts in cerebral localization were added to their knowledge, it was quite generally held that the brain remained non-excitable to electricity, applied from without the skull. The possibility of passing an electric current through the intact skull was first shown by Erb in 1867. In a few years Bouchard and von Ziemssen confirmed Erb's views.

The speaker said that the electric resistance of the cranium impregnated with blood and organic fluids was much less than was generally supposed. Thus Le Duc found that between the electrodes, one placed on the forehead and one on the occiput, there was a resistance of 300 or 400 ohms. Experimentation on the fresh skull showed that the skin, muscles and bone covering the brain had a resistance of but 150 to 200 ohms. Furthermore, von Ziemssen proved that the cerebral substance was the best conductor of electricity in the human body, with the exception of muscle, which was about three times greater than cerebral tissue. Of all the deep-seated organs, the brain was the most accessible to electricity. In view of this it was difficult to understand why brain disorders had remained untreated by electricity. On account of the great volume of muscle intervening, which must first be penetrated from without, the spinal cord was much less easy to reach, yet not a few spinal cord diseases were apparently successfully treated by electricity. In making cerebral applications of electricity one must bear in mind that labyrinthine vertigo was invariably induced if applied from side to side. The vertigo was very unpleasant and should be avoided by applying the current antero-posteriorly, so as to have it spread quite evenly over the hemispheres of the brain. Different brain disorders were being treated by the Le Duc current in this country and abroad, but the tests had not been carried far enough to be spoken of at this time. One of the greatest values of the Le Duc current would be shown in the field of cerebral physiology. By means of the current genuine epileptic fits might be liberated in the brain, and that, too, after the current had been suspended. The amount of potential current able to induce a fit might be definitely established for each animal specie. Then different sedatives might be administered to the animal and the differences of the amount of current showed the strength of the sedative. The accurate therapeutic advantages of this form of experimentation, he said, were quite obvious.

The general effect of the cerebral application of the Le Duc current was highly characteristic of normal sleep. It was not a coma from which the animal slowly recovered. The awakening was instantaneous, as from normal sleep. All bodily functions were resumed as before the application. The future value of the current in special forms of insomnia was obvious. He said it remained for him to speak briefly of his own observations concerning the use of the Le Duc current on all forms of peripheral nerve pain. The relief of all sorts of neuralgic and neuritic pain was instantaneous. The length of time during which pain was abolished varied from two to six hours. As a temporary sedative in locomotor ataxia and facial neuralgia, when the relief from pain for a few hours, even without the use of sedatives, was a matter of great moment, he said he could very heartily recommend the use of the Le Duc current.

Dr. George E. Brewer said that seven or eight months ago, when Dr. Clark suggested to him electro-anesthesia, he was skeptical; but after reading the report of Le Duc, which was so full and convincing in argument, he was glad of an opportunity of watching some observations carried on in the laboratory of surgical research. As the result of the observations he had made, and as the result of Dr. King's and others' experiments, he said he was convinced that in this current they had something extraordinary for the production of anesthesia. On one or two occasions he had seen animals to whom the current had been applied go through identically the same symptoms which followed ether or chloroform narcosis, resulting in the same condition of profound surgical anesthesia. There was this, however, to be said, at the present time, that they were in no position to recommend a trial on the human subject. During October he was able to give a demonstration of this method; he was enabled to show an animal in complete surgical anesthesia upon whom he performed a laparotomy without the evidence of the slightest pain. At that time he said that the procedure was such that he could give no definite prediction. There were some respiratory disturbances in some cases; in some they passed from the condition of excitement into one that threatened the life of the animal. But, on the other hand, without any particular change in the technique or in the current, one found that certain animals responded easily to the influence of the current, passed through the cerebral irritation and excitement into a natural sleep; the general anesthesia appeared superior to one following the use of any other agent. One did not know as yet how long it would be before this method could be used with safety on the human subject; but he believed they were on the eve of a great improvement. It would be a boon to all surgeons if they could have an agent which was devoid of all toxic effects, which did not irritate the lungs and kidneys, and particularly which did away with the often very unpleasant after-effects of the general anesthetics now in use.

Dr. Graeme M. Hammond considered tic douloureux a degenerative process and it did not seem to him that it was curable by any agent known to them at the present time. He compared it with locomotor ataxia; the pains were those of locomotor ataxia; the pains in both conditions disappeared spontaneously. So far as medication went he knew of nothing better than massive doses of strychnine. In his practice he carried the treatment much further, using doses of one-third to one-half a grain three times a day; to reach this dosage, however, required a gradual increase in the dose covering a period of from one year to a year and a half. This treatment should be kept up for two or three years and there would be no period of remissions. He had little experience with the alcohol treatment. He had had one case in which the strychnine treatment appeared to be serviceable for a time, but eventually it failed. The patient was subsequently sent to Dr. Kiliani, who employed the Schlösser method, and success followed the injection. This was a very severe and obstinate case.

Dr. Edward D. Fisher asked if this method of anesthesia possessed any difference from the electrocution method used in Sing Sing.

Dr. I. S. Hirsch said that the current described by Le Duc in February had been employed in the Mt. Sinai laboratory since 1905. In that year this was described as a humane method of electrocution, judging from animal experimentation. The experiments were carried on in rabbits; these animals required more current than dogs. When the current was turned on similar effects were noted as were seen in human beings in the beginning of the anesthesia. There was a period of excitement and the animal gradually fell on the left side. Why the animals fell to that side as a rule he did not know. A very important thing noted in the experiments was the period of inhibition of respiration. Dr. Hirsch said that he was not inclined to be very sanguine regarding the use of this current in the human being.

Dr. James E. King and Prof. F. L. Tufts closed the discussion.

SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Twentieth Annual Session, Held at New Orleans, La., December 17, 18, and 19, 1907.

THE PRESIDENT, DR. HOWARD A. KELLY OF BALTIMORE, IN THE CHAIR.

(*Concluded from page 79.*)

Abdominal Cesarean Section.—Dr. HENRY D FRY of Washington, D. C., discussed the management of labor in minor degrees of pelvic contraction, with especial reference to the relative indications for abdominal cesarean section. He tabulated 18 cases of cesarean section.

Treatment of Diffuse Suppurative Peritonitis.—Dr. STUART MCGUIRE of Richmond, Va., reviewed the work of Muscatello, Clark, Fowler, Bond, Cannon, and Murphy, and stated that the present generally accepted method of treatment had not been adopted empirically, but was the result of deductions from scientific observations. A recent analysis of the last five hundred cases of appendicitis operated on in his private hospital gave a record of twenty-four patients with diffuse suppurative peritonitis. The first six were treated by the old method of irrigation and multiple drainage, with five deaths; the last eighteen were treated by the so-called Fowler-Murphy mehod, with but one death. The difficulty he had experienced in carrying out the treatment was in maintaining the patient in an exaggerated Fowler position. He found by visiting other hospitals that two principles were in practice, angulation of the patient and angulation of the bed. The first was effected by keeping the bed horizontal and elevating the body of the patient by means of a shoulder-rest; the second by elevating the head of the bed and allowing the patient to lie flat on the inclined mattress. The advantage claimed for the semi-sitting position over bed elevation was that it gave better drainage, but this he did not believe to be true, as it was impossible to maintain the patient in the proper position on a shoulder-rest, while it was an easy matter to prevent his slipping on an inclined mattress. The disadvantages of the semi-sitting position were that it made it difficult for the nurse to handle the case, that it was attended by muscular tension and fatigue, and that the patient would slip down so that his body would bend at the costal arch and his abdomen would be on a plane parallel with the surface of the bed. The advantages of elevating the head of the bed are that the mattress might be put at any angle, that the patient lay on the flat surface, often unconscious of his position, and that he was completely relaxed and easily nursed. Dr. McGuire exhibited a model and photographs of an apparatus which he had employed for more than a year to elevate the head of the bed, and to prevent the patient sliding down the incline. The bed elevator consisted of a wooden base and upright piece, with notches on its side. An iron link supported a block which received the leg of the bed. When horizontal, it would slip up or down, but when oblique would catch in one of the notches. The bed-seat consisted of a board which made a shelf on which the patient sat. A wooden shaft projected downward and passed through a second board, which rested against the foot-piece of the bed. In the shaft were a number of holes, and a peg placed in one of them would prevent the shaft passing through the bottom board, and thus transfer the weight of the patient to the foot of the bed.

The Mechanism and Clinic of Pulmonary Embolism.—Drs. WILLARD BARTLETT and R. L. THOMPSON of St. Louis went into the history of the circulation of the blood, thrombosis, and embolism. They discussed the various reasons why thrombus formation took place, stating that it was most common in neighborhoods rich in venous blood. An embolus might float off if there were such thrombi and cause instant death if it plugged the pulmonary artery or one of its main branches, but if the clot was small and lodged in a small lung vessel no symptoms at all might be seen. Attention was called to varicose veins conducting the blood from large abdominal tumors, and the object of the paper was their recognition and treatment. Thrombus formation had attended as high as 5 per cent. of certain long series of operations, while 2 per cent. of the same were attended with fatal pulmonary embolism. The authors reported 22 cases, 16 of them surgical. Autopsy was performed on the majority of the 22. Pulmonary embolism occurred in these cases at intervals varying from one to twenty eight days. Two of their patients recovered, but 20 died, the interval being the onset of pulmonary symptoms and death varying from a few seconds to twelve hours. The symptomatology was considered, as was also the prophylactic treatment.

The Diagnosis of Extrauterine Pregnancy.—Dr. H. J. BOLDT of New York read a paper on this subject. Under the term extrauterine pregnancy he included all fecundations which were situated outside the uterine cavity. While, anatomically, extrauterine pregnancy might be divided into several varieties, from a clinical point of view, such differentiation was not essential. Tubal pregnancy was the most frequent form of ectopic gestation. Uninterrupted extrauterine pregnancy was but rarely recognized, and then usually by mere accident, when operating for other conditions, or when examining a patient for a complaint causing symptoms independent of extrauterine gestation. He had never palpated a tubal pregnancy prior to the occurrence of symptoms due to the pathological implantation of the ovum, except in one instance, a double tubal gestation. In this case, however, the right tubal gestation gave rise to symptoms and was diagnosed. On the opposite side a tubal enlargement was felt, the nature of which was not diagnosed, but on operation the tubal distention proved to be due to a tubal pregnancy which had not begun to be interrupted by bleeding within the tube, or by any inflammatory process about the tube. The distention was limited to the outer two-thirds of the tube, which was freely movable and did not possess the doughy feeling of a pyosalpinx, or the tense elasticity of a hydrosalpinx, which he had supposed to exist on that side. The symptoms were divided into subjective and objective, and these were discussed at length. The absence in the history of the passing of a decidua did not, however, exclude the presence of ectopic gestation. In the large number of extrauterine pregnancies the author had seen, nearly three hundred, less than one-half gave an affirmative history on this point. A decidua might be passed unnoticed, or it might remain in the uterus and eventually be transformed into normal endometrium. After considering the diagnostic features of early extrauterine pregnancy, the author pointed out that after the second half of the gestation period the diagnosis depended on one's ability to determine the presence of a fetus outside of the uterus, which was, as a rule, not very difficult, unless the fetus was located between the folds of the broad ligament, and the woman had thick abdominal walls, or the fetus had been dead for some time, and was not in close contact with the abdominal parieties or the cul-de-sac of Douglas. At this period of gestation the history would aid very much, because in nearly all cases, in addition to the symptoms that were present in the early stages of ectopic pregnancy, there were also in the history symptoms which showed that one or more attacks of local or even general peritonitis had occurred. A pregnancy in the interstitial part of the Fallopian tube caused bulging of the uterine cornu of the invaded side. This bulging, being in an upward direction, necessarily made the cornu much higher than that on the opposite side, and the tube was given off at a much lower plane than that of the impregnated side. In the event of rupture, which

nearly always occurred during the first half of the gestation period, sometimes before the end of the second month, the hemorrhage was very profuse and required rapid intervention. The diagnosis was based upon the determination of pregnancy, with the appreciation of the local findings. Pregnancy in the horn of a bicornate uterus should not cause difficulty in diagnosis, if the pregnancy had gone to the fifth month or more and the fetus was still living. During the first half of gestation, in addition to the subjective symptoms of pregnancy, one should ascertain the presence, alongside the non-impregnated cornu, of the impregnated cornu, which was of a doughy consistency, unless the fetus was dead. In such event, the impregnated uterine horn became harder and more globular, so that it might be mistaken for a pedunculated myoma, or perhaps an ovarian cyst. But if one took all factors into consideration, the history and the objective symptoms to be found on bimanual examination, the diagnosis should not be difficult under ordinary circumstances. It might, however, be quite difficult if the patient was corpulent and had rigid abdominal walls. The greatest difficulty in making a correct diagnosis was in differentiating an ectopic gestation in its early stages from purulent inflammatory conditions of the adnexa, because the latter patients sometimes gave a history identical with that of ectopic gestation, and objectively the tube was distended and firm in consistency. Also the change in the uterus and in the vaginal mucous membrane might be similar. We might have the delayed or omitted menstruation, or atypical bleeding, and he had seen two cases where the blood was similar to that described above as atypical for the bleeding of interrupted extrauterine pregnancy. Furthermore, the character of the pain was sometimes identical, except that no collapse ever followed, as in profuse hemorrhage. He frankly confessed that occasionally in such cases he was unable to make the differential diagnosis without surgical intervention. The error most frequently made by physicians was that of mistaking ectopic gestation for early abortion. Of his ectopic gestation patients who had been curetted by their attendants more had been so treated under the impression that they had had an incomplete abortion than for any other erroneous diagnosis. In taking the history it would be found that with abortion cases the pains usually began with a moderate aching or drawing pain in the lumbar region, radiating toward the hypogastrium. In tubal pregnancy the pains were much more intense and were unilateral in the beginning, and the periods of intermission were generally further apart. Appendicitis might sometimes be mistaken for extrauterine pregnancy, or the opposite error might occur. In an inflammation about the appendix, however, the exudate, if there was one, would be higher up in the pelvis, more toward the iliac fossa. Furthermore, there was always a febrile condition in appendicitis, and none of the symptoms of pregnancy were found unless pregnancy and appendicitis were coexistent. Besides, if one was careful in eliciting a patient's history, there would always be found a difference.

Renal Decapsulation for Chronic Parenchymatous Nephritis.—Dr. J. C. Oliver of Cincinnati presented a full report of the case of a young man upon whom decapsulation of both kidneys was practised for the relief of chronic parenchymatous nephritis. The patient received medical treatment alone for a period of about eight months. At the expiration of that time his condition was much worse than it was at the time he began treatment. In fact, his condition was apparently desperate when a resort to surgical intervention was determined upon. Decapsulation was practised on December 9, 1905. The first favorable sign following operation was an improvement in vision the sixth day. The average secretion of urine prior to operation was from four to fifteen ounces in twenty-four hours. He passed nineteen ounces the day following operation, and by the end of a week this amount had increased to fifty ounces. The preexisting general edema diminished so rapidly that at the end of two weeks one could notice a very decided reduction in the amount. A marked increase in the percentage of urea excreted was associated with the augmented excretion of urine, but the percentage of albumin remained high. This period of miprovement was followed by one of relapse. The edema increased rapidly, and repeated tappings were necessary. The heart exhibited symptoms of gradual dilatation, and there were almost nightly attacks of severe dyspnea. The patient was very ill during January, February, and March, 1906. It became necessary to aspirate both sides of the chest six or seven times during this period. The patient became so desperately ill that his demise was looked for almost daily. A marked improvement took place in his condition about the first of April. The dyspnea diminished, the urine increased in quantity, the edema disappeared entirely, and the patient was able to get up and walk about. The amount of albumin in the urine diminished, and the casts were very much fewer and less granular. The patient was dismissed from the hospital June 8, 1906. During the period from June to October he continued to improve, and he gained in strength to such a degree that he was able to do some light work. There was but little further gain in the eyesight after the primary improvement. The patient was suddenly taken ill during the first week in October. He became comatose, remained in that condition, and at the end of three days expired. There was no return of dropsical conditions. The death was in all probability attributable to the deranged heart.

Inoperable Sarcoma of the Neck.—Dr. Oliver also reported a case of inoperable sarcoma of the neck which was apparently cured by a combination of the use of Coley's toxins with exposure to the action of the Roentgen ray. The treatment extended over a period of five months, at the conclusion of which the tumor masses had entirely disappeared. Nineteen months after the apparent cure a small nodule appeared in the right parotid region. The patient was now receiving injections of the toxins in the hope that these newer manifestations might also prove amenable to the treatment.

Thrombosis and Hydrocele in the Inguinal Canal.—Dr. Joseph Ransohoff of Cincinnati called attention to mild cases of torsion of the cord, of which he reported three cases, following severe strains. In one there had been a hernia, and the condition followed the use of an ill-fitting truss. In none of the cases did thrombosis occur in the subject of a varicocele. Under expectant treatment the thrombosis disappeared. A number of cases of hydrocele of the cord within the canal were presented as a sequence of thrombosis. One was clearly a hematocele and thrombus following an injury. In three other cases the operation showed the thrombosed vein and the hydrocele. One specimen presented was of the rare form of bilocular hydrocele of the canal of Nuck. The patient was 28 years of age. After a strain and slight illness, a hydrocele developed, part of which was in the labium majus, the other properitoneal. The operation, which consisted in total enucleation of the sac, showed a thrombosed vein. The essayist also presented a multilocular hydrocele of the inguinal canal, without any communication with the abdominal cavity, and without any history of trauma. The essayist believed that all cystic tumors within the canal resulted from thrombus and effusion into an unobliterated portion of the vaginal peritoneal process. In his paper he alluded only to cystic conditions of the canal which were secondary to hernias and resulted from the sequestration of a portion of the sac.

Traumatic Epilepsy.—Dr. E. Denegre Martin of New Orleans called attention to the importance of examining all scalp wounds immediately after injury, to determine whether or not fractures might be present, and calling at-

tention to the need of operation at any time that symptoms of cortical irritation were manifested, whether due to or suspected to be of traumatic origin. He reported three interesting cases, one of which was operated upon sixteen years after injury. The man at the time of operation was in such mental condition that he was not able to transact business and was a care to his family. He was relieved by an osteoplastic resection, and was so much benefited that he was able to resume business in a short time, and although he had had several convulsions since the operation his mind was perfectly clear and he felt that he had been greatly benefited. The third case was one of a child who had been struck in the head by a plow-share four years previously. The case had been given up as hopeless, the child presenting the most peculiar symptoms, absolutely unmanageable, and a constant care, with frequent convulsions both day and night. Removal of a segment of bone in this case at the seat of injury resulted in perfect relief and the mental restoration of the child, who, although operated on four years ago, had never had any return of the trouble and continued to improve.

The Value of Intestinal Exclusion as a Surgical Procedure.—Dr. John Young Brown of St. Louis, after discussing the various surgical methods in common use for the restoration of intestinal continuity following artificial anus formation for the relief of gangrenous hernia, reported three interesting cases, in which intestinal exclusion of the afferent and efferent bowel was made, followed by end-to-end anastomosis. The first case was one of strangulated, umbilical hernia, in which the cecum, appendix, ascending and transvere colon were found gangrenous in the sac. At the primary operation an artificial anus was made at the umbilical ring. Ten weeks after this operation the abdomen was opened through a median incision, and bilateral exclusion of the ileum and descending colon was done, followed by direct anastomosis of ileum to sigmoid, anastomosis being made with the Murphy button. The patient made an excellent recovery, and the prolapsed bowel, which remained after intestinal continuity had been restored, was removed later under cocaine anesthesia by clamp and cautery. The second case was one in which an artificial anus was made for a gangrenous inguinal hernia of the right side, the anus being made at the hernial site. In this case a similar procedure was undertaken. The abdomen was opened through the right rectus, the afferent and efferent loop of ileum excluded, and end-to-end anastomosis made with a button. The result was exceedingly satisfactory. The third case was one in which typholotomy was done through a gridiron incision, and at the same time the entire large bowel was excluded except the cecum. The operation was performed after faithful and unsuccessful efforts had been made to relieve an aggravated case of multiple fistulæ and ischiorectal sinuses, with necrosis of the coccyx. It was deemed advisable to turn the fecal current, and this method was resorted to. The turning of the fecal current resulted in healing of the old sinuses. The intestinal continuity was later restored by an exclusion of cecum, and a lateral anastomosis of the ileum to the ascending colon, the last operation being done through an abdominal incision through the right rectus muscle. In each of the cases reported the various steps of the operation were carried out without difficulty, and the results were all that could be wished. Attention was called to the fact that in cases in which an artificial anus was made for the relief of gangrenous hernia the irritation brought about by the constant fecal leakage produced a dense contraction of the scar, which resulted in complete relief of the hernia. By opening the abdomen through an incision away from the original wound the bowel could be excluded and end-to-end anastomosis performed with perfect ease, and without impairing the repair work done by nature in relieving the hernia. The paper concluded with a strong plea for the employment of intestinal exclusion in the treatment of this condition, the writer believing the operation to be safe, surgical, and satisfactory.

Hematuria in Pregnancy.—Dr. Edward A. Balloch of Washington, D. C., surveyed the literature of so-called idiopathic or essential hematuria, or hematuria without demonstrable cause. He showed that most of these cases were in the older literature, and that modern research tended towards skepticism as to the possibility of renal hematuria without some lesion in the kidney. The two principal theories of causation, the angioneurotic and the chronic nephritis theory, were discussed, and the conclusion arrived at that the latter has the weight of evidence in its favor. The writer's case was that of a woman of 31, married at 20, and a 7-para, with a history of almost continuous pregnancies. Blood appeared in the urine during the fifth pregnancy, the hematuria ceasing when the child was born. It skipped the sixth pregnancy, but appeared during the seventh. It did not cease with the birth of this child in March, 1906, but persisted until she came under the writer's observation in October, 1906. She was anemic from the continuous loss of blood, which cystoscopy showed to be from the left kidney. All medical means had been tried without avail. Nephrectomy was advised and accepted, followed by good recovery. After her return home, after operation, she immediately became pregnant. Hematuria was present, but disappeared with the birth of the child. The pathological changes in the kidney were those of glomerular nephritis, with interstitial changes. Accepting the hematuria as a symptom of chronic nephritis, the cause of the latter was discussed and considered to be mainly an autotoxemia from perverted metabolism, of maternal or fetal origin, or both. The influence of a nephrectomy upon subsequent pregnancy was discussed. As this was the second instance in the writer's experience where an uneventful pregnancy had followed a nephrectomy, he did not consider that the loss of one kidney had much effect upon subsequent pregnancy. The cystoscope and ureteral catheter were essential to proper diagnosis. The existence and functional capacity of a second kidney should be demonstrated before operative measures were practised. In the matter of treatment, the author considered that analysis of reported cases showed that equally good results had followed decapsulation and nephrotomy as had followed nephrectomy. He advised the following order of procedure: (1) Injection of adrenalin solution into the pelvis of the kidney. (2) Nephrotomy or decapsulation. (3) Nephrectomy. Nephrectomy should be resorted to only in cases intractable to other measures, as it was essential to save as much of the kidney structure as possible.

The Sensitive Short Uterosacral Ligament; Its Clinical Significance and Treatment.—Dr. Edward J. Ill of Newark, N. J., drew attention to the sensitive short uterosacral ligament as a pathological entity. Schultz and Burrage wrote of the condition long before this. Schultz gave no special advice as to treatment, while Burrage recommended incision of the ligament through an abdominal section. Ovaries had been sacrificed under false apprehension. The condition should not be confounded with intraperitoneal adhesions, nor with shortening of the base of the broad ligament, due to scars resulting from puerperal injuries. Outside of the acute pelvic exudate, the writer knew of no condition so painful on pressure as the short and sensitive uterosacral ligament. During the last twelve years 5 per cent. of all his operative gynecological patients suffered with a short and sensitive uterosacral ligament. When but one ligament was diseased it occurred in 73 per cent. on the left side. The disease might be congenital or acquired either in childhood or during active sexual life. Because of the short ligament a fixation of the uterus resulted. The circulation of the

organ became impaired. Catarrhal and metritic changes resulted in menstrual disturbances. In the acquired case, when but one ligament was short and sensitive, the pain was commonly referred to the sacroiliac synchondrosis or the iliac region of that short side. Menstrual pain seemed to be common to all, and was produced by metritic and endometritic changes. The neurasthenic cases offered a bad prognosis. Sterility was a frequent symptom, and abortion sometimes resulted from a very short ligament. The objective symptoms, when both ligaments were shortened, were to elevate the uterus and drag it into the hollow of the sacrum. Its mobility was much impaired. When one ligament was short the uterus was elevated and displaced to the side of the short ligament and retroposed. The short ligament stood out sharply when the cervix was drawn forward and downward. Great pain resulted from such procedure. The prognosis was bad for those who came from a neurotic family, or where from long-standing conditions the resulting pathological changes had become incurable. The operation suggested by the writer consisted of a most thorough stretching of the tense and sensitive uterosacral ligaments while the patient was under profound anesthesia, until the uterus became freely movable. A free dilatation of the uterus with graduated steel sounds, curettage, etc., should be added.

Cyst of the Pancreas.—Dr. Rufus B. Hall of Cincinnati said that true cysts of the pancreas were retroperitoneal tumors, while pseudocysts were intraperitoneal accumulations of fluid. Judging from the literature, the tail of the pancreas was the favorite anatomical location for the development of these cysts. The diagnosis of pancreatic cysts should be based upon the character of the contents of the tumor rather than upon the supposed demonstration of anatomical connection. The author reported a case of cyst of the pancreas in a woman 42 years of age, upon whom he operated successfully.

Transperitoneal Ureterotomy for Ureteral Calculus.—Dr. Gerry R. Holden of Jacksonville, Fla., reported a case in which he resorted to this operation for the removal of a stone in the ureter. He pointed out the reasons why an abdominal extraperitoneal operation was impossible on account of the thick abdominal walls. He did not believe that transperitoneal ureterotomy for ureteral calculus was often the operation of election. He did believe, however, that it was the best operation when the stone was impacted at or just above the uterine artery, provided one was reasonably assured that infection was either mild or else absent altogether.

The Inconsistencies of the Gauze Pack.—Dr. Hubert A. Royster of Raleigh, N. C., said we drained before we knew why we drained. A strip of gauze was simply a means of applying the law of capillary attraction. Rubber tube and tissue had been substituted, because the gauze so frequently failed to drain, acting as a successful stopper to the outlet. The one thing to be desired was patency of the wound, but there could be no more efficient plug than the stereotyped gauze packing. When intended for a drain, gauze should be inserted after the manner of a lamp wick; when used for hemorrhage, it should be packed in like wadding with a ramrod. There was a field for gauze in packing sinuses, fistulæ, and granulating wounds, so that healing might take place slowly from the bottom. Some would persist in using gauze drains and in the event of disaster would console themselves by believing that it was better to have drained and lost than never to have drained at all. The use of gauze to wall off septic matter in abdominal operations was fraught with danger and full of inconsistencies. The placing of large pads or rolls of gauze in the cavity necessitated a long incision, undue handling of the viscera, and almost always uninfected regions were in contact with pus-soaked gauze. When one end of the gauze was soaked with pus, the other end would become soiled sooner or later. The common practice was to push the gauze packs through pus collections into healthy parts or to wall off around localized abscesses with pads which soon became saturated with purulent products. Exposure of the peritoneum to gauze soaked with pus was just as dangerous as the presence of pus itself among the intestines. A glaring inconsistency was seen in the removal of the packs with contaminated hands. The surgeon should resolve, first, that he would employ gauze sensibly if he could, and not at all if he could not. Second, that if the using of gauze "maketh our technique to offend we will use no more gauze while the world standeth."

Gunshot Wounds of the Abdomen.—Dr. Le Grand Guerry of Columbia read a paper on this subject, in which he reported eight consecutive cases of gunshot wounds of the abdomen.

Suppurative Phlegmonous Gastritis.—Dr. J. Wesley Bovée of Washington, after going extensively into the literature of this subject, reported a case of circumscribed suppurative phlegmonous gastritis in which he resorted to gastrostomy. The case was complicated by pregnancy of six months and abortion. Mrs. T., white, 36 years of age, who had had seven children, followed in 1895 by a miscarriage, was admitted to Columbia Hospital, October 6, 1907. She had suffered from pain in the epigastric region for several years, which was usually relieved by taking food. Her last menstrual period occurred April 13, 1907, and she considered herself pregnant. October 3 she ate heartily of boiled cabbage for dinner and crabs late at night. In the night she was attacked by severe pain in the region of the stomach. Morphia was given for pain. The following day the pain continued and vomiting set in. An attempt to move the bowels by enemata and cathartics was unavailing. The temperature was elevated, ranging from 99.5° to 101.5°. Pulse rapid and weak. The next day croton oil was employed by mouth, but the bowels failed to respond. The various remedies were not effective in relieving the pain, constipation, and vomiting. The vomited material was first solid and partially digested food. Later it was watery and frothy, changing to dark green. She was so enfeebled and appeared to be so ill that the attending physician secured an ambulance and took her to the hospital Sunday night, as mentioned. No chill or sweat was experienced. Dr. Bovée saw her about 11 o'clock that night. At that time her pulse was thready and her countenance anxious in appearance. Examination under anesthesia disclosed the uterus extended to an inch above the umbilicus, and the epigastrium was distended, very tender, and tympanitic. She was promptly anesthetized and in the presence of Dr. Neff and Dr. Dorsey a median line incision above the uterus was made. The intestinal loops were congested, but non-adherent. The stomach was palpated. It was found to be fully three-fourths of an inch thick at the middle of the greater curvature, gradually thinning toward the cardiac end. In the pyloric end and in front was a mass nearly the size of a man's fist that was soft though not doughy to the touch. This gradually thinned out toward the middle of the stomach. The stomach was opened at about its middle by a longitudinal incision at about three inches and the mucosa inspected. To determine the nature of the enlargement more definitely a separate short incision was made over it, when the nature of its contents was manifest. Gauze was passed around it and it was opened and two to three ounces of grayish pus escaped. The long incision was closed and the pus cavity wiped out. A rubber tube was tightly sutured into it and brought out of the abdomen. A light gauze drain was packed about it. She was fed per rectum for twenty-one days. Five days after operation liquids were given by mouth as salt solution by hypodermocylsis and liquids by rectum did not quench her ravenous thirst. The following day the contents of the stomach came through the wound. A few days later solid

food was given and the tube removed. Stomach contents ceased escaping in a few days. On the eighth day, with little effort, she aborted, the fetus living three hours. With the exception of infection of the abdominal incision, which required resuturing, she had made an uninterrupted recovery.

Harmful Involution of the Appendix.—Dr. Robert T. Morris of New York said that most cases of stomach and bowel trouble were not cases of stomach and bowel trouble. Normal involution of the appendix was often a harmful process and produced many of the symptoms ascribed to other organs. Bile-tract adhesions, eyestrain, loose kidney, and several pelvic conditions caused symptoms similar to the ones produced by involution of the appendix. Differential diagnosis was easily made by two features: First, a persistent or frequently recurring sense of discomfort in the appendix region. Second, hypersensitiveness of the right lumbar ganglia. This latter point was of definite and constant diagnostic importance. To find the right lumbar ganglia, draw a line from the navel to the right anterior superior spine of the ilium. An inch and a half from the navel on this line will be found the diagnostic point on deep pressure. McBurney's point was six or eight inches away, at the other end of the line. McBurney's point had reference to acute inflammatory processes in the appendix itself. The point described by Dr. Morris had reference to reflex disturbances caused by the appendix. If the right lumbar ganglia alone were tender on pressure the appendix alone was responsible for disturbances of the stomach and bowel that were ascribed to other causes. If the disturbance proceeded from some organ in the pelvis, both right and left lumbar ganglia were tender. If the disturbance proceeded from the bile tract, or from eyestrain, or some point above the navel, neither the right nor left lumbar ganglia were tender. Dr. Morris referred to the new era of physiological surgery, based upon the studies of Metchnikoff and Wright. The patient would be allowed to do most of the work in managing his infection, and the surgeon was to leave him with such a degree of normal resistance after operation that he could manufacture his phagocytes and opsonins. He thought he stood alone in advocating the doctrine of the new era, but in a year or two more many surgeons would be upholding the doctrine. They would stop doing elaborate work in appendicitis cases with pus, for instance, and they would not fear spreading pus over the normal peritoneum, nor would they stop to remove the pus, provided that they could operate quickly and with so little disturbance to the patient that he was left with his normal resistance unimpaired. The surgeon's function was merely to turn the tide of the battle between bacterium and phagocytes, and they left most of the work for the patient. That was the new principle. Instead of trying to remove the infection by surgery, the infection would be left to be removed by the patient physiologically after turning the tide of battle for him.

Surgery of the Heart and Pericardium.—Dr. Rudolph Matas of New Orleans described the recent advances in the surgery of these organs. According to statistics, the total number of recoveries after operation on the heart was 43.83 per cent. In 134 sutured cases there were 49 recoveries. In 11 cases the heart was exposed without suture and 5 recovered. While the value of statistical conclusions must not be overrated, it might be safely concluded that heart wounds, far from being invariably fatal, gave three chances in four for survival long enough to permit surgical intervention; one chance in ten to heal spontaneously, and one in two to be cured by surgery. Further progress in cardiac surgery could only be accomplished by methods which would diminish three great factors in the mortality—namely, shock, hemorrhage, and infection. The writer then discussed the most recent suggestions which gave promise of decided progress in at least these three directions. First, the diminution of shock by simplifying the preliminary thoracotomy, which gave the operator free access to the pericardium and the heart. (2) By methods of hemostasis which controlled the bleeding from the wounded heart itself, while the suture of the wound was accomplished. (3) Methods which would diminish the tendency to fatal post-operative infection (a) by proper attention to the asepsis, usually neglected in emergencies; (b) by prophylactic drainage of the pericardium and pleura; and (c) by immediate or early obliteration of the pleural space and by the expanded lung to avoid the dead space left by the retracted lung in pneumothorax.

Present Status of Gastric Surgery.—Dr. J. Garland Sherrill of Louisville read a paper on this subject, in which he reported three cases illustrating different conditions for which operation might be done with the hope of materially benefiting the patient's condition.

Case 1.—Man aged 35 years. Gastroenterostomy done for dilatation, which was causing great distress, with the result that the patient had been entirely relieved.

Case 2.—White man aged 50. He gave a history of gastric trouble extending over a period of three and one-half years, with a diagnosis of ulcer of the stomach, with imperfect drainage. The operation in this case consisted of gastrectomy, or removal of the ulcer, and the ulcer-bearing area. The result in this case also was very good.

Case 3.—Woman. Gave history of suffering from indigestion and various stomach disorders for a period of six years, with an interval of quiescence. She had had a number of hemorrhages from the stomach; had lost in flesh, and began to show a cancerous cachexia. Diagnosis of ulcer of the stomach with contracture, probably beginning malignant change, was made. At the operation, which consisted of a gastroenterostomy, a cancerous nodular mass was found involving the lesser curvature of the stomach for three-fourths of its length, and the central portion of the stomach, both anterior and posterior surfaces, for several inches, and the left lobe of the liver, which was closely bound by the growth to the stomach. An anastomosis was made with difficulty, owing to the necessity of making it quite far to the left beyond the border of the tumor. It was possible to complete the operation only after making an opening through the gastrocolic omentum in addition to the one through the transverse mesocolon, and bringing the intestine through both openings and the posterior wall of the stomach through the opening of the greater omentum and there making the anastomosis. After this was accomplished the operation was completed in the usual manner. The patient made a good recovery from the operation, obtained great relief from the gastric discomfort, and had been enabled to take nourishment by the stomach, which was not possible for some time previously. She had developed, however, an edema of the feet which made the hope of her final cure very small.

The following papers were likewise read: "Some Recent Factors in the Elucidation of Chronic Joint Disease," by Dr. C. E. Caldwell of Cincinnati, O.; "(a) Tracheotomy for Foreign Bodies, 53 Successful Cases, (b) Fracture of the Clavicle," by Dr. Willis F. Westmoreland of Atlanta; "Some Remote Symptoms and Effects of Cholelithiasis," by Dr. A. M. Cartledge of Louisville; "Hare-lip and Cleft Palate," by Dr. Alex. Hugh Ferguson of Chicago; "Leverage in Spinal Disease," by Dr. J. D. Bloom of New Orleans; "Suture of the Urethral and Vesical Sphincters for the Cure of Incontinence of Urine, with the Report of a Case," by Dr. Hugh H. Young of Baltimore; "Operation for Relief of Rectovaginal Fistula," by Dr. George H. Noble of Atlanta.

Officers.—*President*, Dr. F. W. Parham of New Orleans, La.; *First Vice-President*, Dr. Willis F. Westmoreland of Atlanta, Ga.; *Second Vice-President* Dr. Henry

D. Fry of Washington, D. C.; *Treasurer*, Dr. Stuart McGuire of Richmond, Va.; *Secretary*, Dr. William D. Haggard of Nashville, Tenn.

St. Louis, Mo., was selected as the place for holding the next annual meeting in 1908.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Connecticut State Board Examinations.

July 9 and 10, 1907.

PHYSIOLOGY.

1. Give the steps in the digestion of a piece of bread and butter.
2. Define and illustrate metabolism.
3. What effect has diet upon the secretion and the constituents of milk? Illustrate.
4. (a) Name the ductless glands and give their functions; (b) What effect has the removal of the thyroid gland (c) and parathyroid?
5. Name in order the cranial nerves, and state whether motor, sensory, or of special sensation.
6. (a) What are leucocytes? (b) Give their functions in the normal body.
7. (a) What nerves control the action of the heart? (b) Locate and give the function of the cardio-inhibitory center and cardio-augmentory center.
8. What are the normal heart sounds? How are they produced?
9. (a) Give a short description of secretion of urine. (b) Upon what does the quantity secreted depend?
10. Enumerate and give the usual time of the eruption of the deciduous teeth, (a) and of their displacement; (b) the permanent teeth.

ANATOMY.

1. Describe the structure and physical properties of bone.
2. Mention in order the varieties of vertebræ and give the distinguishing marks of each variety. Illustrate by pen drawing.
3. Describe the attachments of the sterno-cleido-mastoideus muscle; (b) its function; (c) its value as a "landmark."
4. Describe the brachial plexus. The great sciatic nerve.
5. Describe the portal circulation.
6. Describe Scarpa's triangle; the popliteal space. Give the surgical importance of each.
7. Give a short description of the pleuræ.
8. Describe the uterus, also location, structure, supports, function.
9. Where are Peyer's glands found? What is their size, structure, and function?
10. Give the anatomy of the kidney. Make sketch of the minute anatomy of the same.

CHEMISTRY AND HYGIENE.

1. Give both (a) the normal and (b) the abnormal constituents of the urine. (c) Give a test for sugar and pus.
2. What are the chemical features in (a) disinfection? (b) fermentation? (c) decomposition?
3. What is the chemical explanation of the acidity of normal urine?
4. Give the general composition of living matter.
5. (a) What condition constitutes impure milk? (b) How is it adulterated? (c) What diseases may be spread through the medium of milk? (d) What are the duties of a milk inspector?
6. (a) Should a house water supply become contaminated, how would you detect it? (b) How does sewer gas differ from sewer air?
7. (a) From what sources may chronic lead poisoning arise? (b) Give symptoms and treatment.
8. Give the formula, use, and antidote for corrosive sublimate.
9. In two specimens of urine one is found to have a specific gravity of 1005; the other 1038. Describe the further urinary analysis, and give reports you would make.
10. (a) Define gas. (b) Define laughing gas. (c) Define marsh gas. (d) Define sewer gas. (e) Define diffusion of gases.

MATERIA MEDICA AND THERAPEUTICS.

1. Give the action and therapeutic uses of thyroid extract. (Desiccated thyroid glands.)
2. Give the treatment of the three principal varieties of intestinal parasites.
3. What are the indications for the use of pepsin, for pancreatin, for diastase?
4. What are the preparations and therapeutic uses of benzoin?
5. Name the official preparations of strontium and give their physiological action.
6. What is the physiological action of Fowler's solution? What are its uses and what are the symptoms of overdosage?
7. What is the action of sodium phosphate and what are the therapeutic uses?
8. What are the chemical antidotes for poisoning by the following drugs: bichloride mercury, carbolic acid, strychnine; and what would be their reaction? What would be a physiological antidote for opium?
9. Define an analgesic and state its action centrally and peripherally.
10. Give the physiological action of gelsemium and name some of the indications for its use.

SURGERY.

1. Name three microorganisms which may cause conditions requiring surgical interference, and give clinical symptoms of the form of disease each is most likely to induce.
2. Abdominal palpation, (a) technique, (b) findings and limitations.
3. Spinal anesthesia, (a) technique, (b) dangers.
4. Laboratory diagnosis of hydrophobia; (a) general technique, (b) your view of the reliability of the findings, (c) Pasteur treatment.
5. Diagnosis of intestinal obstruction of the ileum low down.
6. Diagnosis of obstruction at the pylorus.
7. Tracheotomy and intubation of the larynx compared as to (a) indications, (b) contraindication of each.
8. (a) Surgical anatomy of oblique inguinal hernia. (b) In what respects do direct inguinal hernia differ?
9. Diagnosis and treatment of acute middle ear infection.
10. How would you treat intracapsular fracture of the head of the femur on a vigorous patient of sixty? How in a feeble patient of seventy-five?

OBSTETRICS AND GYNECOLOGY.

1. (a) Describe asphyxia neonatorum. (b) How is it prevented? (c) Method of resuscitation.
2. In extraction of the after-coming head, give method of procedure in (a) arrest of head and arm at the superior strait; (b) arrest of an arm behind the occiput; (c) closure of construction ring about the neck.
3. Give causes and treatment of (a) hematocele, (b) cystocele, (c) rectocele.
4. Give the cause, prognosis, and treatment of pernicious vomiting of pregnancy.
5. How would you determine the previous existence of pregnancy in a given case of medicolegal importance?
6. (a) Name all the conditions that may cause delay in the first stage of labor. (b) To what is due the rigidity of the cervix?
7. (a) What is the distinction between presentation and position? (b) Describe the management in posterior positions of the occiput.
8. Give differential diagnosis of extrauterine pregnancy.
9. (a) Give all the causes of post-partum hemorrhage. (b) Give your method of treatment.
10. (a) When is the uterine sound contraindicated? (b) When is the uterine curette indicated?

PRACTICE, PATHOLOGY, AND DIAGNOSIS.

1. What is meant by ptomaine poisoning? Give some of the varieties and the general symptoms in these cases.
2. What is the etiology, the pathology, and what are the symptoms of arteriosclerosis? Mention possible sequels.
3. Differentiate between asthma and emphysema by their symptoms and pathological changes.
4. Name the causes of vomiting; (a) direct, (b) reflex.
5. What are the symptoms and sequelæ of a non-compensating heart?
6. Differentiate between eczema and psoriasis.
7. Give the symptoms of tubercular meningitis.
8. What are the causes and symptoms of obstruction of the ductus communis choledochus?
9. Differentiate pleuritis from intercostal neuralgia.
10. Describe a case of acute poliomyelitis anterior.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

Connecticut State Board Examinations.

July 9 and 10, 1907.

PHYSIOLOGY.

1. *Bread* consists of proteid, fat, carbohydrate, salts, and water. *Butter* consists of fat, a little proteid, and water. In the *mouth*, the ptyalin of the saliva changes starch into dextrin and sugar; in the *stomach*, the proteids are changed into proteoses and peptones; in the *small intestine*, the proteids are further changed into proteoses and peptones and afterwards into leucin and tyrosin, starches are converted into maltose, fats are emulsified and saponified.

2. Metabolism is a name given to the entire series of changes that occur in a cell or organism during the processes of nutrition. It is of two kinds: (1) anabolic, or constructive, and (2) catabolic, or destructive.

3. Too little food decreases both the quantity of milk and the percentage of solids. An ample diet increases both the quantity of milk and the percentage of solids. Abundance of proteids in the food increases the fat in the milk; so also does fat in the food, if it is well digested. Watery food increases the amount of milk, but diminishes the percentage of solids.

4. (*a*) The *ductless* glands are: The spleen, thymus, thyroid, parathyroids, suprarenals, carotid, coccygeal, pituitary, and pineal glands.

The *function of the spleen*.—The following theories have been held: (1) It is a source of production of the white blood corpuscles; (2) it is a source of production of the red blood corpuscles during fetal life; (3) it is a place where the red blood corpuscles are destroyed; (4) uric acid is produced in the spleen; (5) an enzyme is produced in the spleen and is carried by the blood to the pancreas, where it converts the trypsinogen into trypsin.

The *function of the thymus* is not settled; it is said:—(1) to be a blood forming organ; (2) to have influence on growth and nutrition; (3) in hibernating animals it is supposed to store up materials which can be utilized during the period of inactivity.

The *function of the thryroid* is not definitely settled; (1) it has some trophic function; (2) it is supposed to antagonize toxic substances; (3) it produces an internal secretion.

The *function of the suprarenals* is not definitely settled; they produce an internal secretion which is probably necessary to life; it is supposed that they are able to destroy or remove some toxic substance produced elsewhere in the body.

The function of the *other* ductless glands is unknown. They all, or nearly all, furnish an internal secretion.

(*b*) *Removal of the thyroid* causes mental and bodily dullness and apathy, tremors, twitchings, overgrowth of the connective tissues, and development of fat; the hairs fall out, and the patient becomes unwieldy and clumsy in both body and mind. Complete removal causes death in most animals, and it is not considered justifiable in man.

(*c*) Removal of the parathyroid is supposed to cause death; it is believed by some that removal of the thyroid alone does not cause death, but that this is due to loss of the parathyroids only.

6. (*a*) The leucocytes, or white blood cells, are spheroidal masses, varying in size, having no cell wall, and containing one or more nuclei; there are about 7,000 to 10,000 of them in each cubic millimeter of blood. They differ much in appearance, and are divided into (1) small mononuclear leucocytes, or lymphocytes, (2) large mononuclear, (3) transitional, (4) polynuclear, or polymorphonuclear, or neutrophile, and (5) eosinophile. They are all more or less granular, particularly the last two varieties named. They are probably formed in the spleen, lymphatic glands, and lymphoid tissues. Their fate is uncertain; it has been asserted that they are converted into red blood cells; they play a part in the formation of fibrin ferment; they are sometimes converted into pus cells.

(*b*) Their functions are (1) to serve as a protection to the body from the incursions of pathogenic microorganisms; (2) they take some part in the process of the coagulation of the blood; (3) they aid in the absorption of fats and peptones from the intestine; and (4) they help to maintain the proper proteid content of the blood plasma.

7. (*a*) The action of the heart is controlled by:—the pneumogastric nerves and the sympathetic nerves.

(*b*) The *cardio-inhibitory center* is located in the floor of the fourth ventricle; the *cardio-augmentory center* is located in the medulla.

8. The *causes* producing the *first* sound of the heart are not definitely ascertained; the following are supposed to be causatory factors: (1) The vibration and closure of the auriculo-ventricular valves, (2) the muscular sound produced by the contraction of the ventricles, and (3) the cardiac impulse against the chest wall.

The *second* sound is caused by the vibration due to the closure of the semilunar valves.

9. (*b*) The quantity of urine secreted depends upon:—the amount of liquits ingested, the amount of perspiration secreted, the temperature and moisture of the surrounding atmosphere, increase or decrease of blood pressure, and the presence or absence of certain diseases such as diabetes, nephritis, etc.

CHEMISTRY AND HYGIENE.

1. (*a*) The *normal* constituents of the urine are: water; urea; uric acid; hippuric acid; creatinin, extractives; chlorides, phosphates, and sulphates of sodium, potassium, etc.

(*b*) *Abnormal* constituents are:—albumin, sugar, blood, bile, pus, diacetic acid, chyle, mucus, epithelial cells, tube casts, bacteria, parasites.

(*c*) *Test for Sugar*: Render the urine strongly alkaline by addition of Na_2CO_3. Divide about 6 c.c. of the alkaline liquid into two test-tubes. To one test-tube add a very minute quantity of powdered subnitrate of bismuth, to the other as much powdered litharge. Boil the contents of both tubes. The presence of glucose is indicated by a dark or black color of the bismuth powder, the litharge retaining its natural color. (From Witthaus' *Essentials of Chemistry*.)

Chemical test for *pus* in the urine: Acidify the urine with acetic acid, then filter it, and treat the filter with a few drops of freshly prepared tincture of guaiacum; a deep blue color denotes the presence of pus.

2. (*a*) *Disinfection* may be due *chemically* to oxidation, or to the formation of new compounds, or by changing the reaction of the medium containing the bacteria.

(*b*) *Fermentation* is a chemical transformation of *carbohydrates* as the result of the activity of microorganisms.

(*c*) *Decomposition* or putrefaction is a chemical disintegration of *nitrogenous compounds* as the result of the activity of microorganisms.

3. The acidity or normal urine is due, *chiefly*, to monopotassic and monosodic phosphates; *slightly* to carbonic acid; and *indirectly* to uric acid.

4. The general composition of living matter is: water, 75 to 85 per cent.; solids, 15 to 25 per cent. The most important of the solids are *proteids*, which contain: carbon, hydrogen, oxygen, nitrogen, sulphur, and phosphorus.

5. (*a*) Milk is impure when it contains any foreign substance, or any adulterant, or has been skimmed, or in any way differs from the standard of normal milk.

(*b*) Milk may be adulterated by the addition of water (clean or dirty), by skimming, by the addition of coloring matters or preservatives, and by the addition of solid substances, such as sugar, flour, etc.

(*c*) Diseases that may be spread through the medium of milk are:—typhoid, scarlet-fever, tuberculosis, diphtheria, diarrheal diseases, and Asiatic cholera.

(*d*) The duties of a milk inspector are the investigation of milk as to:—color, odor, taste, reaction, specific gravity, acidity, proportion of fat, total solids, determination of albumin, milk-sugar, ash, percentage of cream, presence of preservatives or other added chemicals, coloring matter, dilution, added solids, pathogenic microorganisms, dirt or other foreign matter. There should also be thorough investigation as to its source, the cows and their environment, the method employed in caring for, milking, storing, and transmitting the milk.

6 (*b*) *Sewer gas* "is but a mixture of a number of gases, such as carbonic acid, carburetted hydrogen, ammonium and hydrogen sulphide, nitrogen, etc., together with a considerable amount of fetid organic matters, the volatile or semi-volatile products of animal and vegetable decomposition, varying according to the condition of the sewer, the kind of matter received therein, the amount of surplus water, etc." (Egbert's *Hygiene and Sanitation*.)

Sewer air is atmospheric air with its oxygen diminished and its carbon dioxide increased from 0.04 per cent to 0.4 per cent., and contaminated with more or less marsh gas, sulphuretted hydrogen, ammonium, sulphide, etc.

7. (*a*) The most *common sources of lead poisoning* are the following: "The contamination of drinking water from lead pipes. Contamination of articles of food or drugs by contact with leaden vessels, or from being enclosed in tinfoil containing an excess of lead. Drinking beer, cider, etc., which has been drawn through leaden pipes or allowed to stand in pewter vessels. The ingestion or constant handling of lead or its compounds, as the acetate,

nitrate, carbonate (white lead—painter's colic), Goulard's extract, etc. The use of hair dyes containing lead." (Witthaus' *Essentials of Chemistry.*)

(*b*) The *symptoms* of chronic lead poisoning are: Wrist drop, severe colic around the umbilicus, constipation, feces clay colored, blue line on the gums at the junction with the teeth.

The *treatment* is first to remove the cause; then administer a purge of jalap and calomel combined with opium; iodide of potassium should also be given to help in the elimination of the lead.

8. Corrosive Sublimate. *Formula*: $HgCl_2$. *Use*: It is an antiseptic. *Antidote*: White of egg, followed by an emetic.

10. (*a*) *Gas* is that form of matter in which the molecules constantly endeavor to get away from each other, and so to occupy a greater space; it has neither definite form nor volume.

(*b*) *Laughing gas* is nitrogen monoxide, N_2O.

(*c*) *Marsh gas* is methane, CH_4.

(*d*) *Sewer gas* is the mixture of gases derived from sewers; and see above, question 6 (*b*).

(*e*) *Diffusion of gases* is the spontaneous and gradual passage of one gas into another gas.

MATERIA MEDICA AND THERAPEUTICS.

1. Thyroid Extract. "*Action*: It is a powerful vasomotor dilator, causing flushing of the cutaneous surface; large doses are apt to produce loss of appetite and diarrhea; it stimulates the cerebrum, and, given to excess, produces headache, restlessness, insomnia, palpitations, hot flushes, sweating, tremors, and even convulsions; it is excreted by the kidneys, and the quantity of urine is uniformly increased by it; it induces a greatly increased oxidation in the system.

"*Uses*: Myxedema; goiter (especially the hyperplastic follicular variety); sporadic cretinism; arteriosclerosis; delayed menstruation." (Wilcox's *Materia Medica.*)

2. *Treatment of Tapeworm.* Give a dose of castor oil at night, and the following morning give half a dram of freshly prepared extract of male fern, and a few hours later give another dose of castor oil.

Treatment of Roundworm. A dose of santonin and calomel should be given at bedtime for a few nights, and a dose of castor oil the morning after the last powder.

Treatment of Seatworm, or *Pinworm.* A large enema of a cold infusion of quassia. Care must be taken to prevent reinfection.

4. Benzoin. *Preparations*: Adeps benzoinatus, tinctura benzoini, tinctura benzoini composita, acidum benzoicum, ammonii benzoas, sodii benzoas, lithii benzoas.

Therapeutic uses:—"Locally, wounds, ulcers, old sinuses, etc.; chilblains; the itching of urticaria or eczema; chapped lips, hands, or nipples; catarrhal affections of the pharynx or larynx. Internally, disordered conditions of the urine (as ammoniacal urine and phosphaturia); vesical calculi; chronic gonorrhea; incontinence due to alkalinity of the urine; chronic Bright's disease; diarrheal diseases; respiratory affections." (Wilcox's *Materia Medica.*)

6. The symptoms of *overdosage of Fowler's solution* are:—Nausea, dryness of throat, gastralgia or diarrhea, irritation of conjunctiva or nasal mucous membrane, and particularly a facial edema under the eyes (more noticeable in the morning).

8. The chemical antidote for poisoning by:—Bichloride of mercury is white of egg; by carbolic acid is sodium sulphate; by strychnine is tannic acid.

The reactions are as follows:—Mercury and white of egg give insoluble albuminate of mercury; carbolic acid and sodium sulphate give insoluble sodium sulphocarbolate; strychnine and tannic acid give insoluble tannate of the alkaloid.

Cocaine is thought by some physicians to be a physiological antidote for opium. Strychnine, and atropine and amyl nitrite have also been quoted as physiological antidotes.

9. An *analgesic* is a remedy which relieves pain either by direct depression of the centers of perception and sensation in the cerebrum, or by impairing the conductivity of the sensory nerve fibers. (Potter.)

10. *Action of gelsemium*:—"When given internally gelsemium acts as a powerful depressant to the respiratory, circulatory, and nervous systems. It acts as a depressant to the heart muscle and vagus nerves, and under its influence there is a diminution in the pulse force and blood pressure. It primarily depresses the sensory side of the spinal cord; but later, if given in large amount, depresses the motor side. The drug has no effect upon the spinal nerves, but the motor cranial nerves are paralyzed by large doses. In moderate amounts it causes the respiration to become slow and feeble, and in lethal quantities paralyzes the respiratory centers." (*U. S. Dispensatory.*)

Indications:—Headache, migraine, asthma, whooping cough, nervous cough, spasmodic dysmenorrhea, torticollis, and other conditions depending upon localized muscular spasm.

SURGERY.

3. (*a*) "Not more than one-third of a grain of cocaine should be used. The solution is best prepared by dissolving sterilized cocaine crystals in cerebrospinal fluid, which is drawn into the syringe containing the cocaine after the introduction of the needle into the subarachnoid space. Eucaine, tropacocaine, and stovain may be employed in a similar manner. The strictest asepsis must be practised. The patient lies on the side or assumes the sitting posture; in either case the back should be bent forward in order to increase the space between the vertebral arches. The operator places one finger upon the spine of the fourth lumbar vertebra, which is on a line drawn between the two iliac crests, and enters the needle just below and to the right of this point, in a slightly upward and inward direction, until cerebrospinal fluid escapes, which in the adult is usually at a depth of two and one-half inches. The barrel of the syringe containing the cocaine is now attached to the needle, and sufficient cerebrospinal fluid withdrawn to effect solution. The fluid is then slowly injected, the needle withdrawn, and the puncture sealed with collodion.

(*b*) "The chief dangers are infection, injury to the cord, and poisoning from the anesthetic employed." (Stewart's *Manual of Surgery.*)

OBSTETRICS AND GYNECOLOGY.

2. (*a*) "The body of the fetus should be pushed a little forward in order to diminish the pressure on the arms at the brim, and the child's body should be rotated until its back is directed toward one or other side of the mother. It should then be pressed well forward against the symphysis in order that an attempt may be made to free the arm which is most posterior. The hand is passed upward into the hollow of the sacrum and the first two fingers along the side of the neck behind the posterior arm as far as the elbow. The latter should then be swept over the face and thorax until it comes to lie within the pelvic cavity. The body of the child is then pressed backward against the perineum, and an attempt made to bring down the anterior arm by a proceeding similar to that employed in the case of the other one. Sometimes it is impossible to get room enough to carry out this latter procedure. In such a case the body of the child should be carefully rotated by both hands placed on the thorax, the back of the child moving across the front of the mother's pelvis. The thorax should be well pushed up when this maneuver is begun in order to diminish the risk of dislocating the neck. By this rotation of the back of the child from one side of the mother's pelvis to the other, the arm which was anterior is made to lie posterior, and then it may be more easily drawn down.

(*b*) "In some cases an arm gets jammed over the back of the head between the occiput and the pelvic wall. In freeing it the fingers should be passed up over the back of the fetus, and the arm carefully pushed around the side of the head to its own side. The elbow may then be drawn down over the face and thorax. Sometimes the arm in such a case may be released from its dorsal position by rotating the body in the opposite direction from that which caused the trouble.

"In all these manipulations on the arms there is danger of dislocating the shoulder joint, of separating the epiphysis at the upper end of the humerus, of fracturing the humerus, clavicle, or spine of the scapula, or of injuring nerves. The traction should, therefore, be made in the bend of the elbow. In cases where this method fails, division of the clavicle may be performed—cleidotomy—to diminish the size of the shoulder girdle.

(*c*) "Sometimes the retraction ring of the uterus may grasp the head tightly; sometimes the cervix may be closely retracted on the neck. This condition greatly endangers the life of the child, and delivery must be rapid. The patient should be deeply anesthetized, and traction made on the shoulders and mouth, or forceps should be applied." (Jewett's *Practice of Obstetrics.*)

8. The following tables (from Dorland's *Obstetrics*) give the main points to be looked for in a *differential diagnosis of extrauterine pregnancy*:

From *cornual pregnancy*:

Extrauterine Pregnancy.	Cornual Pregnancy.
Rupture is most prone to take place at some period during the first three months.	Rupture usually occurs between the third and sixth months.
The tumor exists to one or the other side of the uterus, and is usually distinct.	There may be but one tumor, this being dependent upon the degree of bifurcation.
The tumor is exceedingly sensitive and semi-elastic.	The tumor is not so sensitive, and presents the characteristics of a uterine tumor.
The round ligament may be felt attached to the uterus on the inner or uterine side of the gestation sac.	The round ligament is displaced outward and is attached to the external side of the gestation sac.
Examination of the removed specimen shows an absence of true decidual tissue.	True decidual tissue will be found surrounding the fetal membranes.
In interstitial pregnancy the gestation sac communicates with the uterine cavity by the orifice of the Fallopian tube.	The two halves of the uterus are united by a muscular band.

From *pyosalpinx*:

Extrauterine Pregnancy.	Pyosalpinx with Indistinct History of Pregnancy.
The uterus is enlarged, with a soft cervix and the peculiar softening of the body that is present in pregnancy.	The uterus is probably not enlarged, the cervix is not soft, and there is not the elastic feel that is present in pregnancy.
There is a history of sterility, with the signs of endometritis or salpingitis.	There is a history of acute attacks of peritonitis occurring at intervals after an attack of gonnorhea.
The tumor is small, exceedingly sensitive, but, as a rule, not firmly bound down in the pelvic cavity.	The tumor is large, moderately sensitive, firmly bound down in the pelvis, and surrounded by a mass of exuded lymph.
Rupture is likely to occur at some time during the first three months.	The history may have covered a period of months without the symptoms of rupture.
The usual clinical manifestations of pregnancy will be present.	The clinical manifestations of pregnancy are absent or very indistinct.

From *intrauterine pregnancy with fibroid tumor*:

Extrauterine Pregnancy (Tubal Variety).	Intrauterine Pregnancy Complicated with Fibroid Tumor.
There is discovered to one side of the uterus a mass, rounded, exceedingly sensitive, and elastic or semi-fluctuating.	The mass may be rounded; more often it is nodulated, very hard, non-elastic, and non-fluctuating, and not sensitive to the touch.
The uterus is enlarged, but not to a size proportionate to the period of gestation.	The size of the uterus corresponds to, or is even in excess of, the time of gestation.
The menstrual history is irregular, and there may be an early return of the show.	Menstruation is likely to be suppressed.
Rupture occurs at the usual time.	No signs of rupture follow.
Pain is an early and prominent symptom.	Pain develops only after the tumor has reached sufficient size to press upon the surrounding structures.

From *lateral flexion of a pregnant uterus*:

Extrauterine Pregnancy	Intrauterine Pregnancy with Lateral Flexion of the Uterus.
The body and cervix of the enlarged uterus are generally in a straight vertical line.	The fundus lies to one side of the pelvis, with the cervix carried to the opposite side.
The extrauterine gestation sac is in close proximity to the body of the uterus.	A deep sulcus may be felt between the fundus and the cervix.
Anesthetization reveals the mass closely attached to the fundus and readily outlined.	Anesthetization reveals a normal condition of the appendage.
The size of the uterus is much below that indicated by the duration of the pregnancy.	The size of the uterus corresponds to the period of the gestation.
The menstrual history is irregular.	Menstruation is suppressed.
There is a history of severe abdominal pain and rectal tenesmus.	Usually there is no pain other than a backache; there is no rectal tenesmus.

10. (*a*) *The uterine sound is contraindicated in*:—(1) The least suspicion of even the possibility of pregnancy; (2) menstruation; (3) acute endometritis; (4) malignant disease of the uterus or vagina; (5) acute pelvic inflammation.

(*b*) *The uterine curette is indicated in*:—(1) Retained secundines; (2) in some cases of puerperal sepsis; (3) in endometritis; (4) in some cases of carcinoma when hysterectomy is contraindicated; (5) for diagnostic purposes.

PRACTICE, PATHOLOGY, AND DIAGNOSIS.

1. By *ptomain poisoning* is meant poisoning by means of ptomains through the medium of the gastrointestinal canal.

The *chief poisonous ptomains* are:—Tyrotoxicon, mytilotoxin, cholin, neurin, neuridin, putrescin, cadaverin, gadinin, muscarin, tetanin, typhotoxin.

The *general symptoms of ptomain poisoning* are:— Onset in less than twenty-four hours after the ingestion of the noxious "food," chilliness, vertigo, headache, thirst, abdominal pains, nausea, vomiting, diarrhea, cyanosis, rapid pulse, cutaneous eruption sometimes, subnormal temperature at times, convulsions.

2. ARTERIOSCLEROSIS. *Etiology*: Syphilis, alcoholism, gout, Bright's disease, overeating, and excessive muscular exertion. It is most liable to occur in old age.

Possible sequels are:—Thrombosis or cerebral hemorrhage, gangrene of the extremities, interstitial nephritis, angina pectoris, aneurysm, cardiac hypertrophy.

4. (*a*) *Direct vomiting* may be caused by:—Apomorphine, alcohol, inhalation of chloroform, uremia, the infectious and septic diseases, anemia, diabetes, Addison's disease, nephritis.

(*b*) *Reflex vomiting* may be caused by:—Tumor or abscess of the brain; cerebral hemorrhage, thrombosis, or embolism; meningitis; concussion or compression of the brain; emotional or hysterical causes; pregnancy; irritation of the fauces; worms; uterine, tubal, or ovarian disease.

5. *The symptoms and sequelæ of a non-compensating heart* are:—Dyspnea, hemoptysis, cough, chronic bronchial catarrh; congestion of the stomach, intestines, and liver; dyspepsia, gastritis, enlarged spleen, ascites; cyanosis; dropsy; scanty and albuminuous urine, with casts; clubbed fingers; vertigo, headache, or syncope.

6.

Eczema.	Psoriasis.
1. Polymorphous in character.	1. Uniform in character.
2. Generally found on the flexor surfaces.	2. Generally found on the extensor surfaces.
3. The patches are not sharply defined, but gradually merge into the surrounding healthy skin.	3. The patches are sharply defined.
4. Decided serous exudation.	4. Dry scales.
5. Marked itching and burning.	5. No marked itching and burning.
6. Healing begins at the periphery.	6. Healing begins in the center.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.	
Alabama*	W. H. Sanders, Montgomery	Montgomery	
Arizona*	Ancil Martin, Phoenix	Phoenix	April 6
Arkansas*	F. T. Murphy, Brinkley	Little Rock	April 14
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	San Francisco	April 7
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	April 7
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	March 10
Delaware	J. H. Wilson, Dover	Dover	June 16
Dist. of Col'bia	W. C. Woodward, Washington	Washington	April 7
Florida*	J. D. Fernandez, Jacksonville	Ocala	April 13
Georgia	E. R. Anthony, Griffin	Atlanta	May —
Idaho	J. L. Conant, Jr., Genessee	Boise	April 7
Illinois	J. A. Egan, Springfield	Chicago	April —
Indiana	W. T. Gott, 120 State House, Indianapolis	Indianapolis	May 26
Iowa	Louis A. Thomas, Des Moines	Des Moines	March —
Kansas	T. E. Raines, Concordia	Topeka	Feb. 11
Kentucky*	J. N. McCormack, Bowling Green	Louisville	April 28
Louisiana	F. A. LaRue, 211 Camp Street, New Orleans	New Orleans	May 21
Maine	Wm. J. Maybury, Saco	Portland	March 17
Maryland	J. McP. Scott, Hagerstown	Baltimore	June 9
Massachusetts*	E. B. Harvey, State House, Boston	Boston	March 10
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Detroit	June 9
Minnesota	W. S. Fullerton, St. Paul	St. Paul	April 7
Mississippi	J. F. Hunter, Jackson	Jackson	May 12
Missouri	J. A. B. Adcock, Warrensburg	Kansas City... / St. Louis...	April
Montana*	Wm. C. Riddell, Helena	Helena	April 7
Nebraska	E. J. C. Sward, Oakland	Lincoln	Feb. 5
Nevada	S. L. Lee, Carson City	Carson City	Feb. 3
N. Hampshire*	Henry C. Morrison, State Library, Concord	Concord	
New Jersey	J. W. Bennett, Long Branch	Trenton	June 16
New Mexico	B. D. Black, Las Vegas	Santa Fe	June 1
New York	C. F. Wheelock, Univ. of State of New York, Albany	New York / Albany / Syracuse / Buffalo	Feb. 4
N. Carolina*	G. T. Sikes. Grissom	Winston, Salem	May —
N. Dakota	H. M. Wheeler, Grand Forks	Grand Forks	April 7
Ohio	Geo. H. Matson, Columbus	Columbus	June 9
Oklahoma*	J. W. Baker, Enid	Guthrie	
Oregon	B. E. Miller, Portland	Portland	
Pennsylvania	N. C. Schaeffer, Harrisburg	Philadelphia... / Pittsburg	June —
Rhode Island	G. T. Swartz, Providence	Providence	April 2
S. Carolina	W. M. Lester, Columbia	Columbia	June 9
S. Dakota	H. E. McNutt, Aberdeen	Mitchell	July 8
Tennessee*	T. J. Happel, Trenton	Memphis... / Nashville... / Knoxville...	May —
Texas	G. B. Foscue, Waco	Waco	June 16
Utah*	R. W. Fisher, Salt Lake City	Salt Lake City	April 6
Vermont	W. Scott Nay, Underhill	Burlington	July 14
Virginia	R. S. Martin, Stuart	Richmond	June 24
Washington*	C. W. Sharples, Seattle	Spokane	July 7
W. Virginia	H. A. Barbee, Point Pleasant	Parkersburg	April 14
Wisconsin	J. V. Stevens, Jefferson	Madison	July 14
Wyoming	S. B. Miller, Laramie	Laramie	Feb. 12

* No Reciprocity recognized by these States.
† Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

New York and Vermont.—The State Board of Regents of New York has approved the establishment of medical reciprocity between these two States.

Illinois now reciprocates—in the case of physicians' licenses issued after examination—with the following States: Iowa, Kansas, Maine, Maryland, Michigan, Nebraska, New Jersey, North Dakota (after July 1, 1905, only), Ohio, South Carolina, Tennessee, Utah, Vermont, West Virginia, Wisconsin, and Wyoming. Illinois subjects all applicants for a State certificate to practice medicine in Illinois to an examination, in accordance with the provisions of the medical law of the State; but allows, in the examination, a credit of one per cent. on the required average of seventy-five per cent. for each year of reputable practice since graduation, up to a total allowance of thirty per cent.

Virginia reciprocates, under certain conditions, with Delaware, Georgia, Indiana, Kentucky, Maryland, Michigan, Minnesota, Missouri, Nebraska, New Hampshire, South Carolina, Texas, Wisconsin, and West Virginia.

Delaware.—The standard of preliminary requirements has been raised, and a four years' course of seven months each is now demanded of candidates for the licensing examination.

Indiana.—At a meeting of the Indiana State Board of Medical Examiners held July 9, 1907, a resolution was adopted that hereafter students completing the work of the freshman and sophomore years of a reputable medical college may take the examination in anatomy, including histology and embryology, physiology, chemistry, pathology, bacteriology, and such other required subjects as are taught in the freshman and sophomore years of a reputable medical college, at the end of the sophomore year.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending January 11, 1908:

	Cases	Deaths
Tuberculosis Pulmonalis	432	171
Diphtheria	370	42
Measles	691	35
Scarlet Fever	562	49
Smallpox	2	..
Varicella	199	..
Typhoid Fever	55	6
Whooping Cough	24	1
Cerebrospinal Meningitis	16	11
Malarial Fever	..	..
Totals	2351	315

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service for the week ending January 10, 1908:

SMALLPOX—UNITED STATES.

		CASES.	DEATHS.
California, Berkley	Dec. 14–21	1	..

UPON WHAT DOES THE CURE OF TUBERCULOSIS DEPEND?*

BY F. M. POTTENGER, A.M., M.D.,

MONROVIA, CALIFORNIA.

PROFESSOR OF CLINICAL MEDICINE, MEDICAL DEPARTMENT OF THE UNIVERSITY OF SOUTHERN CALIFORNIA.

WHEN we review the overwhelming evidence which establishes the cure of tuberculosis beyond question, it is difficult to explain how the healed lesions escaped the notice of men who were such keen observers of other diseases; yet such is the fact. It is now only fifty years since Brehmer, the first great teacher of the curability of this disease, began his work. He was laughed at and considered insane by his confrères for maintaining that tuberculosis is curable. While he did not live long enough to see its curability universally accepted, yet he was able, before his death, to see sufficient scientific data collected to convince the most skeptical.

These proofs come from two sources: first, from the post-mortem room, and, second, from clinical experience.

There is a German saying to the effect that all men have a little tuberculosis some time in their lives. This is not far from the truth. With the multitudinous opportunities for infection to which we are exposed from early life to old age, it is probable that some time in our lives more bacilli gain entrance into the bodies of nearly all of us than our defensive forces are able to destroy. Consequently an infection occurs. This infection may occur in the lymph glands, or the bacilli may settle permanently in the tissue of some organ either at the point of entrance or after being carried by the blood or lymph stream to some point distant from the port of entry. Although the defensive forces of the body may be such as to be unable to cope with the invading microorganisms at the time of their entrance into the body, yet they may be so augmented by the stimulation resulting from the toxic action of these microorganisms that the disease may be soon overcome and healing result; or, if healing does not result, the focus may become quiescent and remain in a state of inactivity for a longer or shorter time.

That such is the case is proven by the records of all pathological institutes. Tuberculous foci are found in the lungs in from thirty to fifty per cent. of adult persons dying from disease other than tuberculosis. When we remember the frequency of infection of the lymphatic glands, as well as organs other than the lungs, then we can believe it is conservative to say that at least 80 per cent. of the people some time in their lives are infected with tuberculosis, and we can well understand how Schlenker found tuberculous foci in 66 per cent. of 100 post mortems, on persons of all ages, and Burkhardt in 91 per cent. of 1,262 adults, and Naegeli in 97.5 per cent. of 500 cases.

Although tuberculous infection is so common that perhaps 80 persons out of every 100 are infected during their lives, yet only about 11 out of 100 die of the disease. This means that only one dies of the disease, where seven either recover from it or hold it in check so that it does not become active. In the face of these facts we are forced to the conclusion that tuberculosis is not necessarily the deadly disease that we have considered it; in fact, it is cured oftener than it destroys the patient.

There is also ample proof of the curability of this disease from clinical reports. The curability mentioned above, as a rule, has reference to foci so small that they cause few and in many cases no recognizable symptoms; but we still have greater proof. We have proof from the clinician of the healing of a large percentage of cases of tuberculosis when the disease has extended so far as to cause pronounced symptoms, and even of the healing of a fairly large percentage when it has caused very pronounced and in some instances even threatening symptoms.

Where tuberculosis is diagnosed early and treated intelligently, from 65 to 95 per cent. of patients are being apparently cured. And even in the later stages, with cavity formation and serious symptoms, a small percentage can be apparently cured, a great many can secure an arrestment of the disease, and the lives of nearly all can be prolonged. The results obtained by phthisiotherapists the world over, and especially in sanatoria, confirm this statement.

Admitting the above data as correct, the curability of tuberculosis must be accepted as established. It now remains for us to inquire upon what this curability depends. This inquiry will carry us into the discussion of questions of both a theoretical and practical nature; but, inasmuch as an understanding of the theory upon which healing takes place will help in the clinical management of the disease, I believe such an inquiry to be of great importance.

From the bacteriological and physiological standpoints, the important factors in the cure of tuberculosis are the virulence and numbers of the infecting microorganisms and that very important but little understood element known as resisting power.

It is generally known that different strains of the same species of microorganism differ greatly in their virulence. The number of the infecting microorganisms also varies. It is also known that the animal organism is endowed with certain powers which enable it to protect itself from infection. This power, like the virulence and numbers of the microorganisms, varies. Hence, whether or not an infection shall occur, depends upon these variable factors. A few very virulent bacilli might cause an infection in an individual with low resisting power, while many virulent bacilli would undoubtedly over-

*Read before the City and County Society of Portland, Ore., October 16, 1907.

come one with high resisting power. On the other hand, many feebly virulent bacilli would likely be able to infect an individual with low resisting power, although they would be withstood by one with high resisting power.

Not only does this relationship between the virulence or numbers of bacilli, on the one hand, and the resisting power of the patient on the other, determine whether or not infection will occur, but it also determines whether or not a cure will be brought about after an infection has once taken place. In fact, the specific aim in therapy in tuberculosis, as in all infectious diseases, is to raise the resisting power of the individual, so that his body cells may respond to the production of a maximum amount of protective bodies, and thus destroy the invading microorganisms or render the tissues so uncongenial that their virulence will decrease.

The practical importance of this is evident from certain pathological and experimental studies. Pathologically, tubercle bacilli produce several different processes, such as congestion, fibrosis, necrosis, and calcification. As far as the prognosis of the disease is concerned, however, we may say that they stimulate to the production of new tissue and to the destruction of tissue. It has been found that, whether fibrosis or necrosis shall occur, depends upon the toxicity of the bacilli. Where the toxicity of the bacilli is low there is a tendency to the formation of fibroid tissue, and where it is high necrosis predominates. Therefore, it is easy to see how this factor determines whether the case will be an acute one with rapid necrosis and fatal issue, or a chronic one with fibroid tissue predominating.

The important experiments of Störk (*Wiener medizinische Wochenschrift*, July, 1907) upon guinea-pigs bear upon this important subject. By reducing the virulence of bacilli used in inoculating, he has been able to produce a fibroid condition in 100 per cent. of pigs. It has also been shown that dead bacilli have more tendency to stimulate the cells to the formation of fibroid tissue than live bacilli. Therefore, in treatment, measures which lower toxicity tend to healing, and those which increase it favor necrosis.

In accordance with these facts we may assume that in those cases where the individual fails to become infected, although he has taken bacilli into his system (and this doubtless happens very often) the bacilli were either of low virulence or few in numbers, or the resisting power of the patient was high.

In those cases where an infection occurs, but heals out, we must assume that for the time being the virulence of the bacilli or their numbers were too great for the protective forces of the body; but, through some stimulation, the protective forces of the body were increased to such a point that the infectious agents were overcome.

There is a third class of cases in which infection occurs, but the focus, while not healing out, remains quiescent, perhaps with no tendency to extend; or, it may be, with a tendency now and then to extend to new tissue. To this last class belong those cases of tuberculosis which apply to the physician for treatment. We must believe in the former class that there is little difference between the virulence or numbers of bacilli and the protective power of the blood; hence, the infection is not able to extend, but on the other hand the protective forces of the body cannot completely exterminate it. In the latter class the balance is in favor of the bacilli, hence the disease extends.

The tendency to extend is one of the characteristics of tuberculosis as we know it clinically, and the principal reason why the disease is so fatal. This tendency manifests itself wherever the resisting power of the patient is less than the aggressive force of the bacilli. The disease spreads either through the blood, through the excretory channels, or through the lymphatics, the latter being a very common way in which bacilli escape and form new foci in adjacent tissue. It must be perfectly evident then that the larger the focus the greater the opportunity for the escape of bacilli and the greater the danger of the disease spreading.

Modern studies in immunity show that the cure of all infectious diseases depends upon there being present in the organism a relatively high resisting power. They have also shown that protective substances are naturally present in the animal organism, and that when an infection occurs the protective substances in the blood are used up in destroying the invading microorganisms. On the other hand, when the invading microorganisms are destroyed, toxins are set free and thrown into the circulating fluids, where they stimulate the body cells to the formation of specific protective substances, which are again directed against the invaders. Thus the battle continues, the balance being now on the side of the invaders and then on the side of the organism, until one or the other gains the mastery. If healing occurs, it comes because the resisting power of the individual is relatively greater than the attacking force of the germs.

It is now plain that, if the opportunity for bacilli to spread increases with the size of the focus of infection, and, if the protective bodies of the blood are used up in the destruction of the invading bacilli, the larger the foci of infection the greater the opportunity for the escape of bacilli and the greater the demand upon the protective antibodies and the greater the likelihood of their being unable to prevent the extension of the disease.

This offers us the reason for early tuberculosis with a small, limited focus, being so much easier cured than advanced tuberculosis. It also shows us that Nature's method of overcoming the infection is to increase the antibodies of the blood. Thus it gives us the basis of therapy.

If we now turn to the practical side of our subject we will see that the foregoing discussion clears the horizon of much that has befogged the subject of cure in tuberculosis and shows us why tuberculosis is curable, how it is curable, and when it is curable. It shows in what manner the cure depends upon early diagnosis, and suggests the lines of our therapeutic endeavor.

In discussing the practical side of the cure of tuberculosis, the most important point is early diagnosis. Early diagnosis offers the opportunity for treating the patient when the lesion is small, when there is the least opportunity for its spreading to new tissue, and before the constitution of the patient has been seriously weakened.

Early tuberculosis (I mean by this term tuberculosis as we know it clinically) is a disease which will yield in nearly all instances to rational treatment; likewise one which will go on to an advanced condition and cause the death of the patient in nearly all instances where it is treated improperly.

Advanced tuberculosis is not a simple disease, but a complex condition resulting from a disease. As tuberculosis extends there is a destruction of tissue, either necrosis or fibrosis, or both, occurring. Toxins are poured out into the blood stream which

influence every function of the body. The entire organism suffers. While this condition is curable in many instances, it is only cured with great difficulty after an expenditure of great patience and perseverance on the part of both patient and physician, and after the expenditure of much money and time. This condition should not be spoken of as hopeless, for it is far from it; but yet the proportion of cures is quite small when compared with early cases. The difference in results are so great, and the time required to obtain them so much longer, that even when we consider the hopefulness which is attached to advanced tuberculosis when treated by modern, rational methods, we still must urge the fact that our greatest hope comes through early treatment.

Early diagnosis is not sufficient. This means very little to the patient unless it be followed by appropriate treatment. Aside from the fact that early diagnosis offers the opportunity for instituting prophylactic measures in communicable diseases, it is of no value to the patient unless it affords opportunity for the application of remedial measures.

It is now evident that the changes which occur in the organism in tuberculosis are due to the action of both the bacilli and their toxins; hence the cure of the disease must come about by combating these. No matter what remedies or measures are adopted in treatment, their purpose must be to increase the resisting power of the patient toward the tubercle bacilli and their toxins; in other words, to stimulate the cells of the body so that they produce more specific antibodies.

Fresh air is used in the treatment of tuberculosis, not because it has a specific action on this disease, but because living in the fresh air gives one better nerve tone, improves the appetite, aids assimilation, and makes one hardier than those who live indoors. It has this same effect on well people or those suffering from any other illness that it has on the tuberculous. There has been a tendency on the part of many physicians, as well as the laity in general, to believe that the open air is a cure for tuberculosis, that is, that it has a specific action. It is true that we often see patients who will pick up at once when put into the fresh air, and many of these will overcome their disease with little more than this, assisted by good food. We would expect this in such cases as are mentioned above, when the balance between the numbers and virulence of the bacilli and the resisting power of the patient is very small. By putting the patient in the open air his general resisting power is raised, his cells respond better to the formation of antibodies, and his infection is overcome. When this balance is larger, however, when the virulence or number of bacilli is great and the resisting power of the patient is low, then we could not expect a cure from this, even although the resisting power of the patient might be raised to normal.

The action of feeding in tuberculosis is not even as well understood as the use of fresh air. Many of our best known teachers have taught that the greatest desideratum in tuberculosis is to make the patient fat. Acting upon this principle, there is almost no limit to the lengths to which some have gone. We hear of tuberculous patients drinking two and three quarts of milk a day, eating from one to two dozen raw eggs, and besides eating from one to two meals of solid food, and the strange part of this, the almost incredible part of it, is that such diets have been ordered by members of our own profession! Personally, I must plead guilty to having, in my earlier experience, favored forced feeding, but I am glad that I saw my mistake early. I never went to the limit that many have, but I have at times urged more food upon my patients than was good for them.

What can be accomplished by forcing a tuberculous patient to eat two and three times as much as is required by a person in health? In the first place, the chief aim in feeding should be, not the most fat, but the highest state of nutrition. This can only be produced by a selected dietary suited to the digestive, assimilative, and excretory powers of the patient. In tuberculosis all of these functions are impaired, and under these circumstances, let me ask, is it wise or even good common sense to stuff the patient with an amount of food only limited by the ability of the patient to swallow? Such a course cannot help lowering rather than raising nutrition. The answer that is made when this procedure is criticised is that it has produced good results. We must grant that patients will put on weight in this way. Oftentimes they gain enormously, but that is not saying that such a course is best for them. Fat, quickly put on by forced feeding, is readily lost. The patient is not strong; he is not nourished; his tissues are not resistant; at the least provocation he loses much that he has gained. On the other hand, the use of enormous quantities of food overtaxes the digestive and eliminative system, and the patient sooner or later suffers more or less discomfort and finds that his recuperative powers are severely hampered.

We must not lay too much stress upon gaining of weight in tuberculosis. Gaining of weight at any cost is not desirable. Our only aim should be the highest state of nutrition, so that the body cells will respond to the stimulation of the toxins to the production of the greatest number of antitoxins possible.

Thus we can see that fresh air, proper nourishment, regulation of rest and exercise, hydrotherapy, and other tonic measures, are all directed toward one end, that of making the patient resistant. It must not be expected that such measures can make a man infected with tuberculosis more resistant than one who is not. They simply raise his resisting power to the highest point that is consistent with the disease process present.

There is also another element in the natural cure of tuberculosis that is not generally recognized, and that is the escape of toxins from the tubercle bacillus into the circulating media of the body. These stimulate the cells to the formation of protective antibodies, which in turn combat the infection. The manner in which the body cells respond to this stimulation must depend upon the general nutrition of the patient. It is but common sense to expect that well-nourished cells will respond better than poorly-nourished ones.

We might call the cure of tuberculosis in this manner Nature's cure, for it consists in combating the disease by raising the patient's resisting power to a point as near the normal as is possible for him while suffering from the infection, and thus enabling his body cells to respond to the stimulation produced by the toxins which circulate in his body fluids.

One unfortunate thing about the toxins which are thus eliminated is that they are eliminated irregularly, both as to dosage and as to time; consequently the stimulation is not to be relied upon.

Much experimentation has been carried on which has resulted in proving that toxins made from the tubercle bacillis can be introduced artificially, with dosage carefully regulated as to amount and spaced

as to time, which will result in artificially stimulating the body cells to the production of antibodies. Wright has demonstrated an increase of antibodies after inoculation with tubercle bacillus vaccines which amounted to three times that produced by a healthy individual. In fact, when these vaccines are used properly, there is an increase of all those elements which we recognize as accompanying immunity, such as opsonins, agglutinins, and precipitins; there is an increased leucocytosis and an increase in the alkalinity of the blood.

Clinical results also bear out the idea of these vaccines being able to increase the production of protective substances, for many more cases are cured where they are used intelligently than where they are not used. Many clinicians have put them to a very severe test. Where patients were not doing well under ordinary open-air, dietetic measures, they tried the vaccines with a result in many instances of marked benefit.

We can readily see the rationale of this. If the cure of tuberculosis depends upon the production of antibodies in the blood, as we believe it does, then we can see that the more of these antibodies the greater the chances of cure. We can understand how such measures as fresh air, good food, and other tonic procedures are able to cure mild infections where the disease is not too extensive and there are not too many bacilli attempting to escape and form new foci in healthy tissue, and where the infection is not due to bacilli of too great virulence; but we can also understand what a great advantage is afforded these same patients by artificially raising their power to produce protective antibodies by inoculating them with tubercle bacillus vaccines. And we further believe that, in order to cure many of the advanced cases, and especially those where the virulence of the bacilli is great, such inoculations are absolutely necessary.

Such facts are borne out by clinical experience, for when these inoculations are added to the ordinary hygienic, dietetic methods, the disease shows less tendency to spread, the patients develop fewer tuberculous complications, and a greater percentage of cases are cured than where the hygienic, dietetic measures are used alone.

We have now discussed Nature's method of cure, and we have endeavored to show how it can be furthered by proper treatment. In the last analysis, however, the clinical cure of tuberculosis depends upon the intelligent manner in which the disease is managed by the physician in charge and the cooperative response upon the part of the patient. To make an early diagnosis is of no avail to the cure of the disease unless proper measures are at once instituted. It should always be remembered that tuberculosis is a disease fairly easily cured in its incipiency, but cured with great difficulty when allowed to extend, and whether or not it shall be treated in its early stage depends upon the alertness of the members of the medical profession.

Pyometra and Cancer of the Cervix.—Begouin tells us that for the production of a pyometra all that is necessary is a purulent discharge from the endometrium and a stenosis of the cervical canal. This may occur in metritis combined with senile atrophy. It may rarely occur in metritis with cicatricial stenosis of the os, or more commonly in metritis with cancer of the os, the opening being closed by a cancerous vegetation. This is a somewhat rare complication of cancer of the cervix, and is generally diagnosed at the operation instead of before it.

THE DEATH RATE OF THE CITY OF NEW YORK AS AFFECTED BY THE COSMOPOLITAN CHARACTER OF ITS POPULATION.*

By WILLIAM H. GUILFOY, M.D.,

NEW YORK.

REGISTRAR OF RECORDS, DEPARTMENT OF HEALTH, CITY OF NEW YORK.

THE above title suggested itself to the writer by reason of the "marking-time" of the death rate of the city for the past few years in its progress toward an expected lower level, and in the seeking of the causes of the halt in a hitherto uninterrupted decrease, the question as to the part played by the influx into the community of the immense number of immigrants from Continental Europe arose, and therefore this paper.

In a community of four and one-quarter millions of people (a fair estimate of the population of New York City) it is reasonable to suppose that the presence of one and three-quarter millions of "foreign-borners" would appreciably affect the death-rate of the community, especially when we consider that the language, customs, habits, and environments of fully eighty per cent. are so dissimilar in all respects to the requisites established by the authorities for the making of a sanitary member of the body politic. During the fiscal year ending June 30, 1907, the number of aliens arriving at the port of New York was 1,004,000, and of the immense number only 50,000 were credited to Great Britain and Ireland. Well might the student of political, social, and hygienic economy ponder over the question of the assimilative capacity of the country at large and the urban communities particularly!

The crude death-rate as ordinarily used in comparisons of cities and countries is, as you all know, a much-abused weapon of offense and defense, but in comparison of a city's hygienic progress or retrogression with its past it may be depended upon, provided no great change has taken place in the age-grouping, sexual, or occupational conditions. An application of standard death-rates at a series of age-groups to the population of this city as ascertained by the censuses of 1875 and of 1900 was made, and the resulting difference did not exceed one-tenth of one point per thousand in the crude death-rate; therefore, it is allowable to use the death-rate of this city as an index of the prevailing sanitary conditions, and an analysis of the factors affecting its increase or decrease may be indulged in.

In analyzing the tables set forth later on we must not at any time forget that all conclusions drawn are of necessity partly tentative, by the reason of the great stumbling block in the shape of an entire absence of age-grouping among the different nationalities and races comprising the population of the city. Its presence is almost a *sine qua non*, and the means taken to make a substitute therefor consisted in the preparation of a table of deaths and rates from certain causes and in certain districts, the causes being such that affected chiefly certain age-groups, and the districts such as were typical of certain nationalities, races, and age-constitution, thus enabling tolerably fair conclusions to be arrived at.

In Table No. 1 are shown the deaths and death-rates per 100,000 from all causes and from certain prominent causes by nativity of decedents in the old City of New York (present Boroughs of Manhattan

*Read at the annual meeting of the American Public Health Association, October, 1907.

TABLE 1.

DEATHS AND DEATH RATES PER 100,000 ACCORDING TO NATIVITY OF DECEASED IN OLD CITY OF NEW YORK, YEAR 1906.

Nativity of Deceased	Population	All Causes		Typhoid Fever		Pulmonary Tuber'losis		Cancers		Heart Diseases		Broncho-Pneumonia		Lobar Pneumonia		Chronic Bright's	
		D'ths	Rates	D'ths	Rates	D'ths	Rates	D'ths	Rates	D'ths	Rates	D'ths	Rates	D'ths	Rates	D'ths	Rates

and the Bronx) for the year 1906. At first glance at the general death rate column it would seem, if we compare the rate of 1849 per 100,000 of decedents born in the United States with that of 1871 of the entire city for all nativities, that there is very little effect produced on the rate by the mortality among the foreign element, but it must be borne in mind that of 28,067 deaths of natives only 10,080 had American fathers and mothers as parents, the latter figures giving a rate of about 1.440 per 100,000, whilst the rate of 18,067 natives born of foreign parents would be equal to a rate of 2,256 per 100,000; this low mortality of 1,440 per 100,000 among the native Americans and immediate descendants of foreigners would be accepted and conclusions drawn therefrom provided assurance could be given that the age-periods of these two groupings of the population were approximately similar; but that is not the case, as the greater fecundity of the alien produces an undue proportion of children in grouping under five years of age as compared with the native and consequently higher general death-rate results. The difference between the two rates is so great that unequal age constitution does not account for all of the increase; density of population, sanitary surroundings, personal habits and cleanliness, poverty, etc., play a most important part in increasing the mortality among the descendants of aliens.

The general death-rate of each country specified in the table is instructive, though in the comparison of one with the other it is open to the same objection of absence of specific figures as to age-constitution; the Irish lead with a rate of 2,926 and the Swedes apparently are the healthiest with the low rate of 1,121; the high rate among the former being *partly* explainable by the fact that between the years 1847-1893, a period of forty-six years, the influx from Ireland was immense and constant, whilst for the past fourteen years the numbers have been small in comparison, thus producing an Irish population in this city whose age distribution, especially at ages 50 and upwards (assuming the average age of each immigrant to be twenty-five years) is favorable to an exceedingly high death-rate, and the low death among the Swedes being partly explainable by the fact that immigration from Sweden began comparatively at a recent date—1885—and as a result a preponderance of adults is attained at ages between twenty-five and fifty, at which ages the death-rate ranges between ten and twelve per 1,000; what has just been said of Sweden is true to some of the other nationalities, as Italy, Russia, Poland, and Austro-Hungary.

In considering the rates from typhoid fever in this table, remembering that this is a disease that attacks all ages, we find that eschewing the deaths that do not number twenty or over, that the Italians and Austro-Hungarians present the highest rates, at which we do not wonder when we consider their well-known inattention to personal and environal hygiene; the Germans and the Russian Poles on the other hand evidencing the lower rates, the reason in the case of the Germans being the well-known cleanliness of this nation, and of the Russian Poles the prevention of direct infection, most cases among them being removed to hospitals for treatment.

Interesting indeed are the figures presented in the table of mortality from pulmonary tuberculosis. Switzerland leads the list with a rate of 564, Ireland next with 476, Bohemia follows with 438, then Scotland, Austria-Hungary, and Italy in order named, Russia-Poland bringing up the rear with the lower rate of 172. Disregarding Switzerland, as its population numbers only a little over six thousand, and taking up the rate among the Irish, we are confronted with the remarkable rate of nearly 500; this is partially explained by applying the same reasoning to these figures as were given in commenting upon the higher general death-rate among the native Irish, consequent upon the unfavorable age-grouping of the Irish population; the average age at death of the Irish from this disease, based upon two hundred deaths reported, was forty-two years, whilst the average age at death among the entire population based upon over eight thousand deaths, attributed to the cause was thirty-six years; again, the death-rate from this disease in all Ireland in the year 1905 was 204, the rate of the Irish in this city being almost two and one-half times that in their native country. It is hard to believe that this high rate is dependent entirely upon a national predisposition; it is true that we should expect an increase by reason of the comparatively severe climate and the absence of the pure air of the home country, but this is in a measure counterbalanced by the more generous and sustaining food to be had here.

As regards the next cause, cancer and sarcoma, all the foreign natives, with the exception of Italy and Sweden, show a rather high rate, United States showing the lowest rate. Apparently the contention that meat and drink are the predisposing factors in the causation of the ever-increasing mortality from this disease is upheld when we consider that most of the foreign nations specified in the table are placed in the category of the large meat eaters, but this conclusion must not be too hastily jumped at, as the age distribution has considerable to do with the mortality from this disease, everybody recognizing the fact that cancer does not assume a prominent

place in the mortality list until the age of forty has been reached.

In considering the mortality from chronic organic heart and Bright's diseases, the most remarkable thing that can be said is that every nationality bearing a high mortality rate from cancer has a correspondingly high rate from these two causes; if the eye be allowed to run along on a straight line across the table this coincidence is very evident, and what has been said of cancer may be said of these two causes, bearing in mind that these three diseases have during the last fifteen years increased to an alarming extent.

tions drawn from Table No. 1 as to the mortality of the different nationalities from the causes specified; in typhoid fever column, omitting rates whereof the number of deaths does not reach twenty, the Italians and Austro-Hungarians have the highest mortality; under the heading measles we notice that the Italian children have a mortality of almost five times that of the entire city; the Italian children show the highest mortality from scarlet fever and whooping cough, with the Hebrew children a close second; neglect of the use of diphtheria antitoxin produces a mortality rate from diphtheria among the Italian children of three times that of all other nationalities

TABLE 2.

DEATHS AND DEATH RATE PER 100,000 ACCORDING TO NATIVITY

Countries	Population	All Causes		Typhoid Fever		Measles		Scarlet Fever		Whooping Cough

We will now take up the consideration of Table No. 2, which shows the deaths and rates for the same countries and periods as the former table, but based on the nativities of the *parents* of the deceased; the general death-rate column as compared with that of Table No. 1 presents a number of changes, the mortality of decedents whose parents were born in Italy, that is, native Italians and Italian-Americans so-called, reaches the extremely high mark of 3643 per 100,000, or 36.43 per 1,000, though in the previous table the rate of the native Italians is almost one-half of this rate; that of Austro-Hungarians, 1660 per 100,000 in Table No. 1 gives way to one of 2340 in Table No. 2; on the other hand, the mortality of native Americans of 1848 per 100,000 is superseded by a rate of 1398 per 100,000, representing the rate of native Americans and their descendants; the rate of the Irish-born, 2926 per 100,000, gives way to that of 23.55, representing the native Irish and Irish-Americans; in analyzing these rates the disturbing element is the fecundity of the different nationalities upon the mortality rates. The following nationalities have comparatively low birth rates and consequently their general death-rates in Table No. 2 show considerable decreases:

United States, Ireland, Germany, England, Scotland, British America, Switzerland, France, Bohemia and Sweden; considerable increases are shown in those nationalities noted for their opposition to the race-suicide tenets, to wit, Italy, Russia-Poland and Austro-Hungary; the birth-rates among the natives of these countries domiciled in the city have been exceedingly high (probably 32-35 per 1,000) during the past five years, and in consequence the number of children under five years of age preponderate compared with the number of children of corresponding age among the other nationalities, and as the death-rate is very high at these ages we naturally are not surprised at the resulting high mortalities.

Table No. 2 in the main corroborates the deduc-

combined, while among the Hebrew children the rate is almost twice that of the normal average. The mortality from pulmonary tuberculosis, shown in Table No. 2, shows the same general features as that of Table No. 1, the Swiss, Irish, French, Bohemians, and Scotch showing much higher mortalities than the others and than the normal average.

The rates from the cancerous, organic heart, and chronic Bright's diseases are all lower than in Table No. 1, due to the fact that these diseases attack only middle and advanced ages and the rates are figured on all ages, thus including the young children and adults and giving lower mortality figures.

TABLE 3.

Death rates per 1,000 in certain typical square blocks, old city of New York, 1906.

Block	Type	General Death Rate	Pulmonary Tub'r'losis	Cancer	Heart and Brights	Lobar Pneumonia	Broncho Pneumonia	Diarrheal Diseases
A	German	16.30	1.48	2.22	2.96	....	0.74	1.48
B	Austro Hungarian	16.43	1.21	0.72	2.17	1.93	1.93	1.93
C	Russian Pole	17.47	0.83	0.83	1.94	1.04	1.94	1.11
D	Italian	10.26	0.96	....	1.74	0.96	8.29	2.31
E	Bohemian	19.57	4.10	1.82	3.19	...	1.82	1.37
F	Irish	24.64	4.78	....	5.05	0.67	1.91	2.70
G	Chinese	34.65	12.47	0.69	5.54	3.46	0.69	....
H	Syrian	35.83	3.91	1.96	1.30	4.57	3.91	3.91
I	Negro	38.56	8.64	0.66	4.66	2.00	5.99	2.66
Ge	neral rates entire city	18 71	2.30	0 75	2 [illegible]	1 [illegible]	1 [illegible]	1 48

Under the rates from bronchopneumonia, the most surprising rate of the whole table appears, the rate among Italian children reaching the enormous height of 710 per 100,000, more than 7½ times higher than that of American children. When we consider under what conditions the Italian families herd together and the opportunities this affords for the spread of contagious and infectious diseases, the difficulties encountered by the sanitary officers can be imagined but not described. Think of seven tenement houses with a population of 1,500, of a square

block that by actual count harbors 5,100 souls, surrounded by other blocks harboring an average of 2,000, and you obtain an idea of the necessity for eternal vigilance on the part of the health officials.

The lobar pneumonia column reiterates the story as to the Italian national predisposition to disease of the respiratory tract; here the Italian leads, with none of the others a close second.

The mortality from the diarrheal diseases impresses upon the medical profession the necessity of promoting the campaign for a pure milk and food, using our best efforts to advance the worthy cause of a clean milk supply for our large cities with their

death-rate and a high rate in all diseases preponderating at middle or advanced ages.

5. Bohemian Block.—This block shows a moderately high general death-rate and excessively high rate from pulmonary tuberculosis and organic heart disease.

6. Italian Block.—This block shows a general rate slightly above the average but the highest rate from the pneumonias.

7. Russian-Polish Block.—This block shows a low general rate, with a pneumonia death-rate somewhat above the average. The low rates in the Jewish block and throughout the city can be ascribed to

TABLE 2—*Concluded.*

teeming tenements; the death-rate among the Italian children is double that of the Austro-Hungarian and treble that of the average for the entire city.

The third and last table to which your attention is directed shows the death rate per 1,000 from certain diseases and all causes in selected square blocks typical of some of the nationalities and races, the population of these blocks number from 1,400 to 5,100 inhabitants, and are situated in congested areas of the city.

1. The Negro Block.—The influence of the negro's presence upon the mortality rates is always cumulative and is clearly shown in the table; the general rate, 38.56 per 1,000 of the selected negro block (San Juan Hill) is more than double that of the city at large; the rate from pulmonary tuberculosis is three and a half times that of the average for the city and is only succeeded by that of the Chinese block; the mortality from organic heart, chronic Bright's, pneumonias, and diarrheal diseases is also excessively high; throughout the greater city the mortality among the colored population is 27.16 per 1,000, as against one of 18.19 among the whites, the general death-rate being 18.35, the effect of the negro population being to increase the rate by .16 of a point.

2. The Syrian Block.—The recent addition to our community of the Syrian and Armenian section bids fair to affect detrimentally the mortality rates; the general rate of 35.83 per 1,000 almost equals that of the negro block, and the mortality from cancer, pneumonias, and diarrheal diseases is greater than that of the negro.

3. Chinese Block.—This block contains about 1,450 Chinamen and is noted as the block with the highest death-rate from pulmonary tuberculosis, as well as for its unsavory police record; the general rate is 34.65 per 1,000, and it also shows a rate from pneumonia almost as high as that of the Italian block.

4. Irish Block.—This block shows a high general

several causes; although living in densely-populated sections, the Jew, by reason of his temperate habits and his inherited vitality, is able to resist and overcome infection; or, as has been said of the Jew, he is physically "tough" in its best sense; again, the present status of the Jew as to age distribution is favorable at most age-periods, with the exception of under five years.

8. The Austro-Hungarian Block.—This block makes a very presentable showing, the general rate being almost the same as that shown in Table No. 1.

9. The German Block.—This block shows the lowest general death rate, the only rate much above the average being that from cancer.

The conclusions forced upon us by the consideration of these tables are that the natives of Ireland, by reason in great measure of their living at unfavorable age groups, increase the general mortality, and this is also true to a lesser extent of France, Switzerland, and Scotland; the natives of Italy, Bohemia, and United States are credited with a rate almost the same as that of the general average of the city, while the natives of Sweden, Germany, Russia-Poland, Austro-Hungary, and England affect favorably the general mortality.

On the other hand, the immediate descendants of the Irish, Italians, and Austro-Hungarians are instrumental in increasing the general rate and also the rate from certain preventable and infectious diseases; the immediate descendants of most of the other nationalities, including Americans, serve to lower the general rate.

I will close by stating that the Department of Health of the city has, for the past forty years since its organization in 1866, performed wonders with its world-known efforts to stamp out all communicable and infectious disease, and its efforts have left an ineffaceable mark upon the history of sanitary science. Much remains to be done, and it must be you gentlemen who will direct in future the footsteps of the sanitarian in his never-ending work.

REPORT OF A CASE OF ACUTE GASTRECTASIS, FOLLOWING TYPHOID FEVER AND PREMATURE BIRTH; RECOVERY.

By ALBERT E. ROUSSEL, M.D.,

PHILADELPHIA.

ADJUNCT PROPESSDR OF PRACTICE AND CLINICAL MEDICINE, MEDICO CHIRURGICAL COLLEGE; VISITING PHYSICIAN TO THE HOSPITAL OF THE SAME; VISITING PHVSICIAN TO THE HOWARD HOSPITAL: OPPICER OP THE ACADEMY OF FRANCE, ETC.

Until quite recently considerable doubt was expressed as regards the existence of cases of acute dilatation of the stomach, but detailed observations, more particularly by German and English writers, together with, in the greater number of instances, an account of the post-mortem findings prove the question beyond doubt. It may be remarked, however, that analysis of these cases shows a wide variation as regards the etiology and symptoms and even the morbid anatomy, making the diagnosis often a difficult one, which is to be regretted, as an earlier recognition of the nature of these cases would undoubtedly lead to diminish the present high mortality rate.

This is particularly true, as recent observation would seem to add a fruitful cause previously overlooked, namely, the sudden incarceration of the lower end of the duodenum between the root of the mesentery in front and the verterbral column behind (Kundrat, Schnitzler, Albrecht, Muller, Conner, and others).

Neck, in 1905, in a review of the subject collected 60 cases. Lewis A. Conner in a most thorough study (March, 1907) was able to present 102 cases for analysis. In an investigation of the literature since the last date, I have been able to collect 8 additional cases, of two of which, however, I have been unable to procure the detailed reports and which will not be included in this paper. The remaining six, with the inclusion of my own case, would make 109 cases to date. This latter case I will detail at some length.

Mrs. F. White, female, 23 years old, married, height 5 feet 9 inches, weight 160 lbs., no children or miscarriage. Family history is good. Previous history negative. She was admitted in my service at the Howard Hospital on January 11, 1907, suffering from a typical attack of typhoid fever, with rose spots, positive Widal and diazo tests, and remained in the hospital until February 13. The case was free from complications other than a rise of temperature during convalescence lasting four days, accompanied by pain in the right hypochondrium. On March 7, when apparently perfectly well, after a hearty meal of corn beef and cabbage she developed severe pain and marked tenderness in the epigastrium with nausea and vomiting, prostration, and constipation which continued for three days. During this time she was treated by her husband, a senior medical student, by hypodermics of morphine. On March 10 she miscarried at about the seventh month and was delivered by Dr. Raudenbush of a live child without the use of anesthetics. She did well apparently for about 18 hours, when the abdomen became suddenly markedly distended, with little or no pain and no vomiting, but evidences of profound shock. I saw her at this time for the first time since her departure from the hospital. Her condition was apparently an extremely grave one. The radial pulse was practically imperceptible and the heart sounds weak, tumultous and approximating 200 to the minute; respiration 36; temperature 97°. The face and body were deeply cyanosed and covered with a cold perspiration, and although conscious the patient could not speak above a whisper. The most conspicuous feature, however, was a marked distention of the whole upper abdomen which extended downwards to two inches below the umbilicus. The tumor was markedly sensitive on pressure and percussion over this area was absolutely flat. The bowels, which had been opened once on the previous day, were again constipated, but the escape of flatus was observed.

Eight ounces of urine was obtained by catheterization, which on analysis gave the following result: Distinct trace of albumin; no glucose; indican (marked); bile pigments (marked); diazo positive; sediment light; flocculent; sp. gravity, 1030; reaction, acid; color, deep amber; appearance, clear; odor, aromatic; casts, numerous, long and short, hyaline, and finely granular, also a few short, broad hyaline and coarsely granular; cylindroids, a few; leucocytes, a few; epithelial cells, moderate; amorphous urates, a few (Medico-Chirurgical College Laboratory). It may be stated that the many previous examinations of the urine were negative and that the above noted condition did practically disappear one week later.

Diagnosis of acute dilatation of the stomach having been made, the stomach tube was passed with considerable difficulty and three quarts of a dark, sour, offensive liquid was withdrawn together with a large quantity of gas. The relief was almost immediate and the patient was in a much more comfortable condition within one hour. The distention, however, was but little improved but on percussion over this area a high pitched tympanitic note had replaced the former flatness. An analysis of the stomach contents gave the following results: Odor, foul, offensive, blood strong (guaiac test); lactic acid negative or questionable trace; reaction alkaline, HCl absent; bile, trace; starch, negative; albumin, great amount; leucocytes and red cells; amorphous material and shreds of tissue. Subsequent examinations of other specimens gave practically the same results.

Hypodermoclysis was employed. Food and drink stopped by the mouth save a small quantity of cracked ice. Rectal feeding was resorted to and strychnine gr. 1-20 hypodermically was given every three hours together with physostigmine gr. 1-50 every twelve hours. All attempts at the postural treatment both at this time and subsequently had to be abandoned on account of the increase of symptoms. The next day, 18 hours later, the distention again became more marked together with the return of symptoms of collapse, and the tube was passed with the recovery of one quart of fluid similar to the above. Six hours later another quart was withdrawn, twelve hours later another quart, and twelve hours after this a little over a pint was recovered. It will be noted that nothing but small quantities of cracked ice had been taken by mouth during all this time. After repeated efforts of rectal irrigation, the bowels moved on March 12 and an offensive diarrhea began 25 to 35 movements a day, small in amount and containing particles of a gummy greasy substance, were passed. This continued until March 16 and was attended by considerable pain over the abdomen, which subsided with the return of the less frequent stools.

At this time knots of intestines were noticed against the abdominal wall, tense and hard knots disappearing with a gurgle only to reappear at another part. This was accompanied by general pain and tenderness and at these times attacks of

collapse were in evidence which required prompt and vigorous stimulation (nitroglycerin and strychnine).

Nervousness, insomnia, and pain over the wave areas continued for three weeks. On March 28 the distention of the stomach showed marked improvement and feeding by the mouth was begun and continued, but lavage was necessarily continued for over one month. I have recently received word from the husband that his wife is now in perfect health.

The above case presents several points of interest. The length of time after convalescence from typhoid fever (four cases are reported), over one month, would seem to preclude its classification under those following exhausting diseases, and yet it is more than probable that the tissues which had undergone change during that disease had not returned to their normal condition. And although the indiscretion of diet on March 7 was attended by symptoms of acute indigestion, yet there was no visible protrusion of the stomach until March 11, eighteen hours after the occurrence of labor. It is possible that the emptying of the contents of the womb may have had something to do with the occurrence of this condition. (One case is reported following labor.)

The absence of vomiting is exceptional, but was noted in the case reported by Conner. It has been reported present in over 90 per cent. of the cases. The quantity of fluid has in the majority of instances been spoken of as surprisingly large. Indeed Morris has considered this large secretion as the primary cause of the dilatation. The quantity removed from the stomach in my case on different occasions was greatly in excess of the amount of cracked ice which was swallowed.

Again the visible peristaltic waves reported in my case, which lasted three weeks and which might reasonably be expected to be present, are only mentioned in three other instances. Baumler and Herrick saw slight waves and Schultz noticed the same condition for a day.

1. Boas, in his Diseases of the Stomach, American Edition, 1907, makes the following classification of the subject: Gastric paresis after errors in diet. Conner has collected 15 instances to which may be added one of my series, a case reported by Neck, a boy of sixteen when the condition came on soon after eating a great quantity of fruit.

2. After severe infectious diseases such as scarlet fever, pneumonia, typhoid fever, etc., my case makes the fifth following the latter disease.

3. After exhausting chronic diseases. In my collection of cases a consumptive died five hours after the symptom of gastric dilatation. Another, male, suffering from chronic tuberculous caries of the ribs, had an attack of acute dilatation one half hour after taking veronal 0.3. Recovery (Neck).

4. After traumatism. Injury to the head or spine, or even slight blow on the abdomen. Schultz, Fraenkel, Brown, Kelynack, Riedel.

5. After laparatomies. Koberle, M. Gross, Hunter, Grundzach, Robson, Fenger, Kehr, Stieda. Two of the cases in my series, recently reported by Stafford B. Smith (*Journal Med. Asso.*, September 14, 1907, page 941) occurred respectively eleven and fourteen days after operation for appendicitis with one death.

6. Chloroform narcoses alone probably by central paralysis (Morris, Reidel). In most of the operations when the nature of the anesthetic is mentioned, chloroform has been used with the exception of those by Stafford Smith and Herrick.

7. Caused by mechanical kinking of the pylorus on the jejunum or through acute obstruction of the pylorus (gallstones passing into the pylorus). Recent observations of Kundrat, Schnitzler, Albrecht, P. Muller, Conner, and in my series by Neck have exhibited partly torsions of the mesenterium, partly compressions of the duodenojejunal section by the arteria mesaraica superior as causes of such kinking.

Conner, whose classification is somewhat different, has a group of six cases associated with disease and deformity of the spine. He also quotes four cases (W. H. Brown, Miller and Humby, Simon, Wright) for which no cause whatever is assignable.

Three-fourths of the cases occurred during adult life. The youngest case was in a child of three years (Dickinson), the oldest in a woman of sixty-nine (Kundrat).

Sexes.—A slight preponderance of the female sex exists.

Symptoms as a rule come on rapidly, generally within twenty-four hours, especially in the operative cases, and yet in Stafford Smith's cases eleven and fourteen days had elapsed. Most often there is marked abdominal distention extending from the ensiform cartilage sometimes as far down as the pelvis. Vomiting, as has already been mentioned, is nearly always present and where absent may be due to the paresis of the abdominal wall. Profound depression or collapse, weak running pulse, shallow and frequent respiration, normal or subnormal temperature. Intense thirst and scanty or suppressed urine. Pain and tenderness are mentioned in about one-half of the cases and seem to vary considerably in severity. Constipation is noted in the majority of instances where the condition of the bowels is mentioned; as a rule it seems to be of marked degree, but in nine cases diarrhea existed.

Of 102 cases collected by Conner 74 died, giving a mortality of 72.5 per cent.; of the seven detailed additional cases in my collection there were two deaths; a total of 76 deaths out of 109 cases. It is more than probable, however, that if the minor degrees of dilatation were recognized and reported there would be a considerable lowering of the death rate.

In those cases where the duration could be reasonably established it varied from three hours to several weeks. In 75 per cent. of the fatal cases the duration was less than five days. (Conner.)

Seventy-one autopsies are on record. In all of these cases is mentioned the enormous size of the stomach and generally a thinning of the walls. The duodenum was dilated in thirty-nine cases, and in twenty of these the dilatation stopped suddenly behind the root of the mesentery where the compression existed.

The causes assigned for acute dilatation are varied. In the nonobstructive cases, particularly in those following abdominal operation, it has been assumed to be of a paralytic nature. Herf assumes that this paralysis may be due to the excretion of chloroform by the stomach. Albu attributes it to the absorption of toxins. Pepper and Stengel consider that the pyloric stenosis may be due to spasm the result of acute indigestion or hyperacid secretion.

Conner has collected eighteen cases in which the autopsies showed mesenteric constriction of the duodenum. The autopsy made by Neck (my series) may be included in this division. It would seem therefore that this condition had been overlooked in some at least of the other cases and that from this time on more careful search in this direction

will result in proving its existence in a still larger percentage of cases. Besides which the cases in which the postural treatment was employed and resulted in recovery were probably of this nature.

The diagnosis is not as difficult as might be thought, if the possibility of the occurrence is borne in mind. It is possible that many cases of uncontrollable vomiting after operations may be due to this cause. The vomiting as a rule is more constant and the pain less than in volvulus of the stomach, which may closely resemble it in other respects. The occurrence of a visible protuberance and the information gained by the passage of the stomach tube are of great importance. The fluid should not be fecal in character and may contain bile or even pancreatic juice. Kelling suggests the use of a high injection of a 0.6 per cent. salt solution to determine whether complete obstruction of the duodenum exists. This as a rule will empty the small intestine and the presence or absence of fresh bile would determine the question.

In the treatment, early and frequent lavage is an absolute necessity and may, if employed early after an operation, even prevent its occurrence. In a number of the recent cases reported the placing of the patient in the knee-elbow position or on the belly has been followed by prompt and satisfactory results. (Schnitzler, Baumler, Müller, Waltzberg, Robson). It is to be remembered, however, that similar treatment in my case aggravated the symptoms, and the report of a like result is made by Borchardt. Water and food should be administered by rectum together with, if necessary, the employment of hypodermoclysis. Strychnine, atropine, physostigmine, and nitroglycerin should be employed. Saline purgatives in small and repeated doses may be required when the more acute symptoms have subsided.

The results obtained by operation for the relief of this condition as collected by Conner have been unsatisfactory. In seven instances (W. H. Brown, Box and Wallace, Appel, Hoffman, Jessop, Kirch, Wright) the stomach was opened and evacuated but none of the patients recovered. Gastroenterostomy has been performed twice (Kehr, Korte) and both times unsuccessfully. Petit found at operation a sharp kink in the duodenojejunal junction. This he relieved by lifting up the jejunum and stitching it to the transverse mesocolon. The symptoms disappeared and the patient recovered. The advisability of a gastroenterostomy is open to serious question. There is quite general agreement that it should be employed if at all, only as a last resort. In most cases it is unnecessary, and in those patients who have resisted all other methods of treatment it is doubtful, Borchardt thinks, if any good can be accomplished by operative measures.

CHANCROIDAL BUBO AND ITS TREATMENT.*

By HENRY H. MORTON, M.D.,

Brooklyn, N. Y.

Prof. Genitourinary Diseases in the L. I. College Hospital, Genitourinary Surgeon to Long Island and Kings County Hospitals and to Polhemus Memorial Clinic.

Enlargement of the inguinal glands occurs in 30 to 50 per cent. of all cases of chancroid. It is a serious accident to a working man because the inflammatory swelling is painful and necessitates stopping his work and remaining in bed; and under the former plan of treatment by excision, a large open wound was left, which remained six or eight weeks before it was healed.

It was formerly thought that the lymphatic glands became swollen from the irritation of toxins, but it is now known that the toxins are not responsible, but Ducrey's bacillus (the specific organism of the chancroid) is the active agent. It is easy to demonstrate the presence of Ducrey's bacillus by incising the bubo, scraping its walls, and examining the pus under the microscope. Twenty-four hours after opening the bubo, mixed infection occurs, and the streptococcus can be found.

It has been found that with the presence of chancroids, heavy physical exercise tends to the development of buboes, and for this reason women, whose work is not as laborious as that of men, are less liable to suffer from them. Another frequent cause

*Read before the Brooklyn Medical Association, May 8, 1907.

for the formation of bubo is the improper treatment of the chancroid. An attempt to destroy its specific character by cauterizing it with nitrate of silver stick is not only useless, but is often directly responsible for the formation of bubo. The cauterizing action of nitrate of silver, is very superficial and not sufficient to destroy Ducrey's bacillus, and its only effect is to form a crust over the sore. Thus the organisms cannot escape from the wound but make their way into the lymph glands and a bubo is very apt to form.

One gland alone may be enlarged, but as a rule, the whole chain on one side is affected and it is not infrequent for glands on both sides to be involved.

The anatomical structure of the lymphatic vessels communicating with each other and anastomosing explains the fact that the chancroid may be on the left side of the penis and the bubo on the right side, or *vice versa*, or the chancroid and bubo may be on the same side.

While in general the chancroid is still visible when the bubo is forming, it occasionally happens that the sore has healed or indeed in some cases the chancroid has been so insignificant as not to have attracted attention, and the bubo appears to have formed spontaneously. The French describe this condition as *bubo d'emblée*, and for many years its etiology was obscure, but to-day the fact is established that a bubo is always caused by a sore on the penis or lower part of the body, which in exceptional cases may have healed at the time the bubo first appeared.

In cachectic and debilitated individuals, a bubo may break down and slough and become connected with a true chancroidal ulceration which extends over a large area and becomes in its course a serpiginous or sloughing chancroid.

In making a diagnosis of bubo, the difference in the sensation on palpation of the glands will often indicate whether the enlargement is due to syphilis or whether from a chancroid. The difference is well characterized by Lesser, who described the syphilitic adenopathy as being in the form of a rosary, while the chancroidal bubo resembles a packet.

Among the other possibilities to bear in mind are undescended testicle, hernia, and tuberculosis or cancer of the inguinal glands.

It was formerly supposed that, if a bubo could be seen in the early stages before suppuration had begun, the glands might be dissected out, the wound closed by suture, and healing by primary union obtained.

I have seen possibly 200 cases of bubo, but have almost never seen one in which suppuration had not begun in the central part of the gland when it was exposed by dissection; in consequence of this the wound is always infected and primary union does not take place. A deep gaping cavity is left which usually takes from four to eight weeks to heal by granulation.

The attempt to bring the granulating surfaces together after a few days by suture has also always met with failure, and as most of these cases are treated in hospitals, a bed which is required for an active case must be given up to a granulating bubo.

Another objection to the early excision of bubo is the frequent occurrence of elephantiasis of the scrotum and penis subsequently, from the closing up of the lymphatic vessels in the healing of the cavity.

It is true that occasionally a bubo will be met with which does not soften under hot applications and these of course must be excised and curetted out, but they are largely in the minority.

The treatment which I desire to advocate to-night was suggested to me by a visit to the Charité in Berlin, summer before last, and since then I have used it in the Long Island College Hospital and the Kings County Hospital with most gratifying results.

When a bubo first appears, an attempt should always be made to prevent suppuration by putting the patient to bed. The ice bag, which was formerly so popular, is no longer used because it has been found that resolution will take place just as well with warm applications. Injection into the substance of the gland of antiseptic solutions, such as nitrate of silver, carbolic acid, and bichloride of mercury, has also been abandoned as useless.

A common method in the Charité in Berlin is to cover the bubo with gauze, wet with 95 per cent. alcohol, covered with cotton wadding and perforated gutta percha tissue to prevent too rapid evaporation. The alcohol is renewed twice a day as it evaporates. Another method in common use is fomentation with solution of acetate of ammonia used warm and frequently renewed. Tincture of iodine has little or no value as an absorbent.

After fluctuation has begun the warm applications should be changed for hot ones, to encourage rapid breaking down of the glands.

The thermolyte bags are useful, as they can be used with the hot fomentations and serve to retain the heat for a long time.

After the bubo is thoroughly broken down and full of pus, a small incision is made with a double-edged knife and the pus evacuated. A 10 per cent. iodoform-glycerin emulsion is then injected into the wound. The injection is made three times at the first sitting, the first two injections being allowed to run out and the last one retained. The wound is then bandaged over night with fomentations of solution of the acetate of ammonium.

On the following day the bubo is emptied by squeezing out and the injection is again made three times, the two first injections running out and the last one remaining in. The wound is then bandaged and left undisturbed for five or six days. At the end of that time, in the great majority of cases the bubo is healed and the patient requires no further treatment.

I append a detailed report of thirteen cases, kindly prepared for me by Dr. J. Sturdivant Read. Five cases occurred in my service at Long Island College Hospital, six cases in my department at the Polhemus clinic and two cases were private patients of Dr. Read. These patients were all cured in from seven to ten days after they were incised and injected with a 10 per cent. iodoform-glycerin emulsion.

Cases Treated in Long Island College Hospital.

1. N. N., sailor, admitted November 11. Right bubo, gonorrheal, indurated, large, one small area of suppuration. Incised—small amount of pus; iodoform injections. In bed ten days. Complete recovery in two weeks.

2. C. P., sailor. Admitted December 11. Right bubo, gonorrheal, large, soft, fluctuation marked. Iodoform injections. In bed one week. Complete recovery.

3. G. S., sailor. Admitted December 18. Right bubo; gonorrheal, suppuration well advanced. Incised; iodoform injections. Complete recovery in six days.

4. Tonzio, sailor. December 17. Double bubo, gonorrheal. Left showed marked fluctuation. Incised; iodoform injections. In bed seven days;

complete recovery in ten days. The right bubo, which was indurated on admission, continued so. There was no sign of change in its condition and the patient refused to remain in the hospital.

5. Fuer, sailor. Admitted December 23. Right bubo, gonorrheal, large and fluctuating. Incised; iodoform injections. Good recovery in eight days.

Cases Treated in Genitourinary Department of Polhemus Clinic.

6. January 1, T. G., Italy, bartender, 28 years old, single. Chancroids appeared two weeks ago; swelling in groin began four days later. Examination shows suppurating bubo on left side. Incised, small amount of pus; injected. He remained quiet about the room four days; went to work on the fifth day, as there was no pain. Bubo on seventh day much improved. Washed with peroxide and reinjected. Reported one week later cured.

7. January 12, W. B., U. S., clerk, 22 years, single. Gonorrhea and chancroids for last two weeks. Examination shows soft bubo on the left side. Incised, about three drams of pus being evacuated; injected with iodoform. Reported three days later to dispensary. Wound improved. Cleansed with peroxide of hydrogen and reinjected. One week later improvement so marked that he was allowed to return to work. January 22 discharged cured.

8. January 29, T. M., U. S., telegrapher, 24 years, single. Chancroids four weeks ago; has had large swelling in groin for ten days. Examination shows large suppurating bubo on the right side. Incised and injected. In bed one week. Complete recovery at end of ten days.

9. T. J., U. S., carpenter, 33 years old. Chancroid appeared on the frenum three weeks ago; bubo developed on the left side which became very painful in the last week. Examination shows small bubo with one soft area. Incised, about one dram of pus being evacuated; injected. February 28 reports that after rest in the house one week he went to work again. Examination shows all suppuration to have disappeared. No tenderness remains.

10. February 26, J. K., U. S., laborer, 28 years, single. Chancroids on foreskin and frenum appeared two weeks ago. One week later swelling in right groin began. Examination showed inguinal bubo. No area of suppuration. Sent home and poultices ordered for two days. On return a small area of suppuration was found. The bubo was incised and injected. Order to stay in bed five days. On examination at end of that time wound was healing rapidly; it was cleansed with peroxide of hydrogen and reinjected. March 7, discharged cured.

11. March 28, H. B., U. S., 34 years, single, laborer. Has had chancroids for three weeks. Examination shows fluctuating bubo on the left side. Incised and injected. Reported to dispensary April 6, saying he stayed in the house one week, at end of which time he returned to work. Examination showed wound practically healed; no sign of inflammation.

12. November 3, 1905, P. D., undertaker, 26 years, single. Denies any previous venereal history. Five weeks ago he first noticed sores on the penis; one week later the bubo developed, which has been increasing in size and discomfort ever since. There are two chancroids on the foreskin, one on the frenum, and a bubo on the right groin, large and fluctuating. The pus had burrowed down the inner side of the thigh. A single incision was made, one and one-half inches long, at the point of the greatest softening, giving exit to thick yellow pus. Injected with iodoform emulsion. At the end of a week he reported, much improved. Reinjected. Seen two weeks later, the patient said he did not come back, as it "healed right up."

13. December 4, 1905, S. J., laborer, 26 years, single. Three chancroids, one on frenum, appeared three weeks ago. Period of incubation uncertain. Bubo on the left side is hard, painful, and hot. Patient was in bed two days, with hot applications. On December 7, suppuration was beginning. The bubo was incised, giving exit to about 2 ounces of pus. Injected with iodoform emulsion. Repeated injection three days later. At the end of a week he was much improved; no pain, slight induration, no suppuration or discharge. Patient promised to report again, but failed to do so.

SYPHILITIC FEVER, WITH REPORT OF A CASE.*

By E. D. NEWMAN, M.D.,

NEWARK, N. J.

DERMATOLOGIST TO THE ST. JAMES AND GERMAN HOSPITALS.

Medical writers, including syphilographers, give scant space to the description of this fever; the authors of the various articles published vary widely as to when the pyrexia concomitant with syphilis should be called "syphilitic fever."

Guntz's[1] description of a true syphilitic fever is one with rather an insidious invasion, occurring during the second incubation, and preceding the outbreak of the first eruption; generally occurring about two months after infection, sometimes as late as three months. The type of the fever may be continuous, intermittent, or remittent; very rarely, indeed, is it accompanied by great prostration, headache, epistaxis, etc., and it may then assume a typhoid character.

With a true chancre sometimes a bubo suppurates and the formation may be attended by a rise of temperature, but this would not be syphilitic fever. Again we see that in the cachectic condition of tertiary syphilis, with the bone and the visceral lesions, in brain syphilis, etc., a rise of temperature is one of the clinical features of the affection; yet this is not syphilitic fever.

Lowenburg[2] declares syphilitic fever should not be confounded with the commonly recognized fever occurring during the early period of the secondary stage of syphilis. It is a *late* manifestation, and occurs more often in those who have inherited the taint than those who have had a primary sore.

Futcher[3] says the fever may occur at any time after the appearance of the chancre—as early as three to four weeks before the secondary rash, or at any time during the course of the secondary or tertiary periods.

Musser[4] calls attention to an intermittent type which may occur as the initial fever or in the tertiary stage.

Osler[5] follows the description of Guntz.

Ravogli[6] asserts that syphilitic fever has nothing to do with fevers arising late from gummatous ulcer, or from osseous complications, due to the action of the common pus cocci.

Carrière's[7] description of the fever is similar to that of Guntz, and he declares that after a careful scrutiny of the literature he finds only 25 cases; since his article there have been reported 6 cases, 1 each by Lowenburg,[2] McKenna,[8] and Birt,[9] and

*Case reported at a meeting of the Physicians' Club, October 12, 1907.

3 by Rolleston.[10 11] Of these 6 cases only 2 would come under the head of syphilitic fever as described by Guntz and Carrière. McKenna's case was a child 9 years of age afflicted with heredo-syphilis. Lowenburg's and Birt's cases were of fever in the tertiary period. Of the 3 cases reported by Rolleston, one was a case of heredo-syphilis and enteric fever; the other 2 were cases simulating typhoid fever, and occurred in the secondary period.

Fournier[12] coined the word "typhose" to emphasize and to designate that condition met with in certain cases of syphilis which closely simulates typhoid fever.

Because of our lack of positive knowledge of the contagium and its relation to the many pathological changes, the disease must be approached from the clinical side and therefore the chances of error are many. Keyes, Musser, and others make mention that in cases of obscure fever it should be borne in mind that the cause thereof may be a syphilitic infection, particularly when we recall that fever may occur in syphilis apart from any other special manifestation, such as iritis, adenopathy, periostitis, etc.

To the cases reported we can add one in which the early course of the fever simulated typhoid to a most remarkable degree, but in which the diagnosis was made comparatively easily at the time when the general eruption was in evidence; while the eruption was sparse and scattered, the diagnosis of an accidental rash of typhoid fever was considered; it was my good fortune to see a case of the latter while the case of syphilitic fever was under observation. For the history of this case I am indebted to Dr. Frank Gordon.

J. F., male, aged 20, bookkeeper; family history negative; previous history, measles, mumps, whooping cough and scarlatina. Three months ago had an infected heel, which was incised and treated surgically; vaccinated successfully six years ago. His employer had just recovered from an attack of typhoid fever.

Present illness, August 10, 1907; he attended to his labors, but felt badly and went to bed early. The second day he was unable to eat breakfast, had some headache and abdominal pain, went to his work but was compelled to return home at noon; was seen by Dr. Gordon in the afternoon; temperature 105° by the mouth, pulse 130, spleen enlarged. Patient complained of severe pain in the back of the neck; had an attack of epistaxis while the doctor was present, and then recalled a previous attack one week before. On the third day the temperature was 104°, pulse, 120, no sweating, complained of pain in the abdomen and in the back of the neck; prescribed calomel, grs. 10.

Fourth day: Morning temperature 99°, afternoon temperature 100°; spleen still palpable, but not so large; found a rose spot on the abdomen; the patient began to have a slight cough, but was much brighter and very hungry. Patient of his own accord took calomel, grs. 2, that evening, also in the evening of the fifth and sixth days, when the doctor was informed and the drug was ordered discontinued.

Fifth day: Had a severe epistaxis; temperature, A.M. 99.5°, P.M. 100.5°; two more rose spots found on abdomen, gurgling in right iliac fossa, no tympanites, no vomiting, slight cough persisting.

Sixth day: Temperature, A.M. 100.5°, P.M. 101.5°; no more rose spots; toward night there was a general erythema. Had marked "tache cerebrale."

Seventh day: General condition about the same; erythema disappeared; no more rose spots; slept poorly.

Eighth day: About same; irritable; refused medicine; still complained of pain in the abdomen and in the back of the neck; photophobia; more spots on the abdomen.

Ninth day: Many more spots on the abdomen, bright rose in color and fading on pressure; a few look like pimples. Temperature, A.M. 101.5°, P.M. 102.5°. Began to complain of sore throat; on inspection fauces were found congested, no patches; a few rose spots on forearms. A second Widal examination was negative.

Tenth day: I saw the patient in consultation with Dr. Gordon. Temperature 103°, pulse 120; tongue heavily coated and moist; intense pharyngitis and uvulitis; two patches of leucoplakia, one on inner surface of right cheek, the other below the central incisors of the lower jaw. Cervical and inguinal glands slightly enlarged, epitrochlears not palpable; in the right femoral region was a nest of small glands distinctly palpable and exceedingly painful on examination. Tenderness in right iliac region, and decided gurgling. A slight discharge from the urethra was noticed for the first time; microscopic examination revealed no gonococci.

Eruption was a typical secondary maculo-papular syphilide, very extensive in character, especially marked on forehead, hands, and feet; on each patella was a papular ring made up of a large number of small papules; around the meatus urinarius was a group of papules and a thickening could be felt along the floor of the urethra.

Under treatment by mercurial inunctions the urethral discharge ceased in thirty-six hours, and the temperature was reduced to normal in seventy-two hours; the patient continued to do well for twenty-five days, when inunctions were stopped and he was placed on protiodide of mercury; two weeks later the patient complained of rheumatic pains in the shoulders, wrists, and sternum; temperature 102.2°, pulse 130. Inunction treatment was renewed, with prompt removal of all symptoms.

In a comparison with typhoid fever, Potain [13] says just at the commencement of the secondary period there may light up a fever with the mucous plaques that will have all the appearance of typhoid, but while there may be great prostration, and even stupor, there will not be any pain on palpation of the right iliac region, nor any gurgling there. This statement is not in accord with those of other observers, as Carrière mentions in his symptomatology, a tense and painful abdomen and the presence of gurgling; in this case the patient had abdominal pain increased by pressure on the second day and gurgling was noticed on the fifth day; both of these symptoms persisted until after the beginning of the mercurial inunctions.

The initial temperature of 105° is not common; the drop in temperature on the fourth day, which lasted about seventy-two hours, was undoubtedly caused by the calomel, showing the effect of mercury on this fever.

A transitory erythema mentioned by Futcher[1] was observed in this case in the evening of the sixth day. An unwonted excess in the appetite (bulimia) is sometimes a feature of early syphilis, and was particularly pronounced in this case on the fourth day.

The urethral discharge was probably due to the papular eruption occurring within the urethra; this symptom I could find mentioned in only one reported case.[1]

Why does syphilis assume such a febrile condition in some cases? Carrière gives three hypotheses: (1) The syphilitic microbe is hypervirulent; (2) these cases are instances of concomitant secondary infection; (3) it is due to the poor, badly defended ground upon which syphilis has fallen. His conclusions are that there is nothing which enables us to say that syphilitic typhosis is due to hypervirulent infection; that it is not due to any secondary infection nor to any heightened influence of the intestinal microbe; there is a probable element of truth that syphilis has fallen upon badly defended ground.

Jacobi[14] contends that these persons who suffer so severely do so because the disease has never been present in their forefathers, or at all events not for a long time previously, so they are not safeguarded by an acquired immunity.

Westphalen[15] claims that the pyrexia is due neither to the absorption of necrotic material nor to the special viscus affected, but to the natural reaction against the *Spirochæta pallida* or its toxins.

Ravogli[6] gives as a reason for the pyrexia that it is the result either of the chemical products emanating from the metabolism of the syphilitic microorganisms, or from the products of disintegration of the blood or of the tissues, which in the general circulation are liable to produce this peculiar pathological symptom of general reaction. Burke,[16] in an article on scarlet fever, contends as to hypervirulency that if the blood and tissues previous to the advent of an infection were toxic laden there will be a better culture medium for the growth of the infecting germ. During the infective process the immunizing and the curative powers of the body are persistently called into play; under favorable conditions the leucocytes are rapidly produced and liberated into the circulation, to digest and destroy the invading entity, bacteria, protozoa, or toxin; in the battle of the leucocytes with bacteria or protozoa, both the leucocytes and the unicellular invaders are killed in countless numbers, until one or the other force prevails.

Rosenau and Anderson,[17] in their laboratory experiments, show that the phenomenon of hypersusceptibility has been produced in the guinea pig, by extracts obtained from the colon bacillus, yeast, hay bacillus, anthrax, tubercle bacillus, and the typhoid bacillus. From their experiments they believe that the problem of hypersusceptibility has an important bearing upon the question of immunity; their work indicates that hypersusceptibility is either an essential element or one stage in the process of resistance to a certain class of diseases. It would seem from an analysis of these various opinions that the pyrexia of syphilitic fever is due to a hypervirulent infection upon a medium that is unable to combat the infecting protozoa, because of a loss of that immunity which had been transmitted or acquired.

THE SURGICAL VALUE OF IODINE.*

By WALTER T. DANNREUTHER, M.D.,
NEW YORK.
ASSISTANT SURGEON, ST. BARTHOLOMEW'S CLINIC.

Iodine is obtained from seaweed, in the form of mineral iodates and iodides. Every physician is familiar with its physical and chemical properties, physiological action, and therapeutic uses and advantages. The efficacy of the internal administration of iodine, especially in the form of iodides, when indicated, is well appreciated, and I could add little or nothing to what is already known in this direction. Probably physicians have equally as much knowledge of the indications for iodine in surgical conditions. But have they fully appreciated the *value* of the use of iodine in surgery? From my experience with iodine in hospital and clinical work, I have been convinced that it is an agent of high germicidal potency, one of the most valuable antiseptics in our armamentarium, and endowed with remarkable penetrating power. I have used it extensively and for a variety of conditions, and the results have been exceedingly gratifying. A number of practitioners object to using iodine freely because of its cost. But we have one form of iodine available for surgical use, *i.e.* the tincture, which is comparatively cheap; for whether we are using it full strength or well diluted, only a small quantity is required. Of course, the ideal "iodine antiseptic" is the pure iodine vapor, but as far as I am aware, no compound has yet been produced which will yield iodine vapor in any considerable amount, except iodine itself; and used in this manner, it would indeed be an expensive antiseptic. Iodoform was formerly believed to have this property, and was largely used in surgical dressings as a dusting powder and incorporated in gauze. Although iodoform contains 96 per cent. iodine, the consensus of opinion to-day seems to be that iodoform is practically valueless, except for such quantity of iodine as may be liberated and come in direct contact with the tissues, which occurs very slowly as a rule. In spite of this fact, the only four cases of iodism I have seen (iodine being present in the urine) have occurred as the result of iodoform. So are we not justified in concluding that, although the rapid absorption of iodine is the very thing we wish to promote, when this occasionally does take place, we are apt to get the full toxic effect? Aristol, a substitution compound containing 45 per cent. iodine, is another agent that has been used to a considerable extent in preference to iodoform, because it is less toxic. But its antiseptic powers are feeble, it is expensive, and the results of its employment have not been satisfactory. Iodol, nosophen, eudoxin, and many others have been similarly advocated. But why depart from our pharmacopœia unnecessarily? I have used the ordinary tincture (U. S. P.) repeatedly, and have not had a single case of iodism occur. It is imperative that we obtain a freshly prepared tincture (as the alcohol evaporates on standing), and use enough but *not too much*. Do not apply as much to mucous membranes and granulation tissues as to the unbroken skin. Used with care, except for an occasional use of iodiosyncrasy, we should never

*Read before the Tri-Professional Medical Society, New York City, November 19, 1907.

see even the slightest indication of iodism. I have found a watery solution of iodine, made by adding 5i of the tincture of iodine to Oii of water, very useful.

Minor Surgery.—The ordinary tincture of iodine is probably more frequently utilized as a counterirritant for localized uncomplicated inflammations than in any other class of conditions. We find it very satisfactory applied to the superimposed skin, in simple bursitis, synovitis, tenosynovitis, etc., and it is also used advantageously in similar medical conditions, such as acute pleurisy and sciatica. The skin is lightly painted with the tincture of iodine and allowed to dry. Desquamation will occur in a day or two, and we may then repeat the application if necessary. For these conditions I have frequently employed a modification of the tincture, viz., Elsberg's solution, which is a 20 per cent. solution in alcohol and ether, while the tincture is a 7 per cent. alcoholic solution. This will produce the same results as three coats of the ordinary tincture, dries rapidly, and will not soil the clothing. I have found this preparation exceedingly valuable in the treatment of lymphangitis (before the formation of pus, of course).

Every hospital interne, especially the house surgeon of a city hospital, has an almost unlimited number of wounds of all descriptions to care for during his service. In my service at the Jersey City Hospital, I had perhaps eight hundred patients with such wounds. We all know what the ordinary scalp wound looks like; laceration, hemorrhage, dirt, hair, and sometimes vermin. And even with thorough cleansing, suture, and gauze dressing (and dusting powders), we find that many of these wounds become infected, and if neglected, subsequently, the pus may undermine the whole scalp. I have made it my practice in all scalp, incised, punctured, and lacerated wounds after thorough shaving, washing with green soap and water, and otherwise procuring cleanliness as nearly as possible, to inject tincture of iodine directly into the wound, with an ordinary medicine dropper. Enough sutures are then introduced to obtain complete coaptation, and a wet gauze dressing applied. It is important that this dressing be kept wet until there is primary union. Every such wound, treated in this manner, which has had the proper after-treatment faithfully and conscientiously carried out, *has healed by primary union*. I consider this the very best method of procuring sterilization of a dirty wound. A case which has had dirty instruments, etc., used at the second or third dressing, we cannot expect to recover in this manner. And I do not include such conditions as a complete laceration of the thigh, from Poupart's ligament to the knee, where there is a great deal of contusion. Here sloughing naturally occurs, and iodine or any other such agent will not prevent it. It will, however, limit the formation of pus. In such a case, free drainage with constant hot wet dressings is a much better procedure than sutures.

I have had twelve cases of erysipelas. Each one was treated by painting the eruption and a generous border of the healthy surrounding skin with tincture of iodine, and in no case was there any extension of the erysipelatous rash. Of course, appropriate internal medication was used in conjunction.

Iodine will be found useful for stimulating sluggish granulations, such as an indolent ulcer. Apply the pure tincture directly to the granulation tissue. In the treatment of gangrenous ulcers, the direct application of tincture of iodine will limit the extension of the process, hasten sloughing, lessen discharge, and act as a deodorant.

Major Surgery.—Iodine has been used in many ways as a method of sterilization for the hands. Perhaps the most common is thorough scrubbing with green soap and water followed by immersion of the hands in a 1 per cent. watery solution of iodine and potassium iodide. Jeffries, of the New York Polyclinic, found by bacteriological laboratory experiment that this will render the hands sterile in thirty seconds. The operator may dip his hands frequently into a basin containing this solution during the course of the operation. The amount of staining of the skin is inconsiderable and may be readily removed with ammonia water. In fact, some operators use the full strength tincture in this manner. In the *Deutsche Zeitschrift für Chirurgie*, Vol. 87, Nos. 4 and 6, Heusner recommends a mixture of iodine and benzin used in this way, as being superior to all other methods. His formula is iodine 10 gm., benzin 750 gm., and paraffin 250 gm. He pours half a pint of this mixture into a porcelain dish, and scrubs his hands with it.

Tincture of iodine is an excellent agent for disinfecting the skin before an incision for laparotomy, especially in the region of the umbilicus. One application with a camel's hair brush is all that is necessary. Heusner uses his mixture, suggested above, for this purpose also.

One of the most valuable ways in which iodine has been recently used is in the preparation of "iodized catgut." Claudius of Copenhagen first devised this method. He takes the raw strands and immerses them in a 1 per cent. watery solution of iodine and potassium iodide, and allows them to remain in this solution until he wishes to use them. But if left for a considerable length of time, the catgut becomes very brittle. Alexis V. Moschcowitz of the Mt. Sinai Hospital has modified Claudius's procedure, in that he leaves the catgut in the solution for eight days only, and then keeps it in dry sterile gauze. The advantages of catgut prepared in this manner are that it is antiseptic as well as aseptic; its tensile strength and pliability are increased, and it is exceedingly cheap. Willard Bartlett further modifies this method. He suggests heating the strands in liquid albolene over a sand bath at a temperature of 320° F. for one hour, before immersion in the iodine solution. This toughens the gut very much, at the same time making it more pliable, and gives us a thoroughly satisfactory suture material.

Goelet of the New York School of Clinical Medicine uses a watery solution (one dram of the tincture to two pints of water) for irrigating the abdominal wound after closing the peritoneum, and has found it very satisfactory. My own personal experience in this respect has been somewhat limited, but I believe it to be an excellent means of securing sterilization of a laparotomy wound.

Gynecology.—I know of no other single agent as valuable as iodine in the early stages of gonorrhea in the female. To Goelet, the credit is due for introducing this method of treatment. I have followed his technique in all such cases occurring in my hospital service and private practice and the results have been brilliant. The patient empties her bladder, and a solution of iodine (one-half dram of the tincture to two pints of water) is injected directly into the urethra and bladder, allowed to remain for a minute or two, and then voided. This is repeated daily until edema of the vulva appears. The injections are now replaced by potassium permanganate douches, 1-5000. The bowels, diet, habits, etc., are to be regulated in the usual way, and Basham's mixture administered internally.

Iodine will be found very valuable incorporated in a tampon (one dram of the tincture to four ounces of glycerine) as a method of procuring pelvic counterirritation.

Subsequent to a curettage for endometritis, an intrauterine douche of the watery solution (one dram of the tincture to two pints of water) will limit oozing, contract the muscular fibers, and render the uterine cavity sterile. After a curettage for abortion, I have frequently swabbed out the uterus with the full strength tincture. Should the abortion be septic, an intrauterine iodine douche three times a day will control the septic process better than anything else that I know of.

Obstetrics.—After labor, an intrauterine iodine douche at 106° F. will act as a prophylactic against possible infection and post-partum hemorrhage. It stimulates and hastens contractions of the uterus, acts as an antiseptic, and constricts the mouths of the blood-vessels. I have used such a douche as a routine procedure, immediately after the expression of the placenta, in all my cases, and as yet have not had puerperal sepsis or post-partum hemorrhage occur in any instance. During my hospital service, there were two cases of post-partum hemorrhage admitted as such, and the intrauterine douche at 116° F. readily checked the bleeding. There were also three cases of puerperal sepsis admitted. In each one I used a tri-daily intrauterine douche, and the result was three uneventful recoveries. It is always wise to take the precaution to lubricate the adjacent skin area and buttocks with vaselin, or some other emolient, to guard against a possible excoriation of the skin by the iodine.

Genitourinary Diseases.—Tincture of iodine applied to the skin over a bubo (before the formation of pus) will produce the same effects as in any other lymphangitis. The tincture mixed with glycerin has given good results in the treatment of hydrocele. The sac is emptied of its contents, the mixture injected, and then allowed to escape. This causes considerable pain, so that it is well to use a general anesthetic.

As yet, I have had no experience with iodine as a method of treatment for gonorrhea in the male, but feel confident that in the future iodine will be found as valuable for treating this condition in the male as in the female. Sternberg (*American Journal of the Medical Sciences,* April, 1883) experimented with gonoccoci and found that iodine entirely destroyed them in a solution of 1 to 4000.

I make no claims for originality in any of the methods of using iodine enumerated in this paper, and perhaps I have omitted to mention a number of ways in which it may be satisfactorily utilized. There are many other conditions in which we may use iodine to advantage after future investigation. Why not flush out the peritoneal cavity with a weak solution of iodine, after a laparotomy for peritonitis? Would not the subcutaneous injection of iodine hasten the process of repair in a delayed-union fracture? Would not iodine be a satisfactory agent to apply to a carbolic acid burn, because of its marked antagonism to carbolic acid? My sole purpose has been to report the results of the use of iodine in my experience, and endeavor to instigate a little more interest in, and experimentation with, this agent than it has heretofore received. I do not believe that the value of iodine in surgery is as generally appreciated as it deserves, and present this paper with the hope that it may develop further research in this direction.

2030 Broadway.

CARBOLIC GANGRENE.

By ISAAC LEVIN, M.D.,

NEW YORK.

Notwithstanding the fact that a great many publications have appeared in the last quarter of a century reporting cases of gangrene of fingers caused by the application of a dilute solution of carbolic acid, this drug is still dispensed freely by druggists and used extensively as an antiseptic home remedy. And not only the laity, but a great many physicians, retain the erroneous and long ago scientifically disproven impression, that carbolic acid is one of the best remedies in combating a bacterial invasion. V. Kenerson,[1] who reports a case of carbolic gangrene, says that carbolic acid is the best penetrating disinfectant in those infections that do not proceed from an open wound, as it has real penetrating power through unbroken skin, but it should never be covered with any material that will prevent evaporation and should be applied only with a light dressing.

Lucas Championnière,[2] who also reports two cases of carbolic gangrene, does not advise against the use of the remedy, but thinks that the danger of it may be minimized by dissolving the acid in glycerin instead of water or alcohol. There is no doubt that carbolic acid is a very dangerous remedy in untrained hands, no matter how dissolved or applied, and this fact cannot be emphasized too strongly or too often. I shall therefore report the two cases of carbolic acid gangrene that came under my observation lately and review the whole matter anew.

Case I.—The first patient was a young man of twenty-five years, a pianist by profession. A cat scratched the fourth finger of his left hand. Afraid of a possible infection, he went into a drug store, where a carbolic acid solution was applied, without an impermeable tissue or tight bandaging. The patient continued the same application for the next six hours, when he came to his house physician (Dr.

S. Short) complaining of an uncomfortable sensation in the finger. Dr. Short, suspecting that the sensation might be due to the carbolic acid, sent the patient to my office. On examination I found the terminal and a part of the middle phalanges of the fourth left finger completely anemic, not sensitive to touch, temperature, or pain, but found no general disease, no sugar in the urine. I applied a dry sterile dressing for twenty-four hours. On the next day the diseased part of the finger looked already wrinkled, grayish-white in color, and formation of a dry gangrene commenced. In a few days complete demarcation took place and I then exarticulated the finger in the metacarpo-phalangeal joint. The patient made an uneventful recovery. The high exarticulation was done instead of a partial amputation for cosmetic purposes. The accompanying illustration from a photograph shows well the line of demarcation and the shriveled condition of the gangrenous part of the finger.

Case II.—The second patient was a girl twenty years of age. She scratched her right index finger with a rusty nail. To prevent "blood poisoning" she bought carbolic "water" in the drug store and applied it for twenty-four hours. At the end of this time she began to get a strange numb feeling in her finger and went to her physician. The latter apparently did not recognize the condition, and ordered her to continue the carbolic application, which the patient did for the next three days and then came to see me. On examination I found the terminal phalanx of the right index finger somewhat shriveled and the skin all over the terminal and on the plantar surface of the middle phalanges perfectly dry and black. I made the diagnosis of carbolic acid gangrene, applied a dry sterile dressing and decided to wait for the appearance of a line of demarcation. When in ten days the latter still did not appear, I gradually peeled off the gangrenous part and found that it only went as deep as the cuticle, and underneath I found a new, healthy skin. It seems to happen very seldom that carbolic acid gangrene does not ocupy the whole thickness of the part involved and stops at the skin. David Wallace[3] reports such a case.

The following two cases occurred in the practice of Prof. F. C. Wood. They have never been reported, and, with his kind permission, I report them here.

Case III.—St. Luke's Dispensary, May, 1897. The patient was a large, powerful, healthy working man, who had accidentally scratched the index finger of his right hand and for about two days had noticed considerable redness, swelling, and pain. He went to a druggist and asked for some application for the finger. The druggist sold him "carbolic acid" and told him to put the carbolic on a cloth, wrap it around the finger, and leave it there. This was done and the rag was kept moist for about twenty-four hours. When he came to the clinic the rag had been removed for about twelve hours. The skin over the two terminal phalanges was black and dry, and the tissue shrunken. There was a sharp line of demarcation. There was no sensation on thrusting a needle into the tissues. The man desired to have his finger amputated so that he could return to work more quickly. This was done and primary union resulted.

Case IV.—A similar case entered the dispensary about one month later. This was a butcher who had infected his finger and had, also, applied to a druggist and obtained "carbolic acid." He used this for twenty-four hours and noticed that the pain stopped. Amputation was also necessary in this case. The conditions were identical with those previously described.

Various explanations were given to this gangrene produced by a local application of a dilute solution of carbolic acid. Kortum[4] thinks that the acid acts on the trophic or vascular nerves. Frankenburger[5] explains the formation of the gangrene by a destruction of the red and white blood corpuscles inside of the capillaries and subsequent thrombosis, stasis of circulation, and gangrene. The experiments of Levai[6] led him to dismiss both the opinions of Kortum and Frankenburger. He showed that 5 per cent. solution of carbolic acid and different other mineral acids, when applied to an extremity by a moistened compress for twenty-four hours produced a gangrene and that this gangrene is due to a direct chemical action of the acid on all parts of the tissues. "The histological examination shows that in the beginning each of the diluted chemicals applied in the form of a moist dressing produces the same effect: the epithelial layer becomes edematous and loosened." "As soon as a way has been made to the deeper layers each agent produces in a different way the same result, namely, necrosis of the living tissues."

All these theories, ingenious as they are, do not explain the fact that only in a small percentage of cases where a moist carbolic acid compress is applied does gangrene develop. They do not explain, for instance, the peculiar difference in my two cases. In the first case the carbolic acid was applied only for six hours and there developed a complete gangrene, while in the second case only a superficial gangrene of the skin took place after a continuous application of the acid for four days. Apparently in order to produce its deleterious effect the carbolic acid must meet with a certain lack of resistance either of the whole organism or only of the organ to which the acid is applied. Of course, it is impossible to tell whether the power of resistance of the tissue cells is diminished, or, as is most probably the case in Raynaud's disease and in spontaneous gangrene, the capillaries of the predisposed individual contract easily, producing subsequently ischemia, stasis of circulation, and gangrene. The latter supposition seems to coincide well with the facts that carbolic gangrene usually takes place in extremities—fingers—and always begins with a severe local anemia.

While by far not in every case where an application of a dilute solution of carbolic acid is made does a gangrene set in, the cases are sufficiently numerous, and every patient applying a carbolic compress for a trifling injury probably does not take much less chance of a gangrene than the patient taking general anesthesia does of ether death. But is carbolic acid just as indispensable as general anesthesia, or rather, is it needed at all? Lister, the brilliant discoverer of the antiseptic treatment of wounds, recommended carbolic acid, under the impression that every pathogenic germ, whether found in the air or on the surface of the body of the patient or inside of tissue cell, has to be killed by an effective germicide drug, and carbolic acid is certainly one of them. But it is a number of years since antisepsis in surgery was superseded by asepsis. We have learned that in the majority of cases the organism, through its fluids and leucocytes, is able to neutralize the pathogenic organisms invading it. The aim of the surgeon nowadays in the treatment of every wound consists in removing by mechanical cleaning the pathogenic bacteria from the skin, protecting from new invasion by an aseptic dressing and draining off well the wound secretions.

Poisonous drugs like carbolic acid only injure and diminish the vitality of the tissue cells, and the more so the greater their "penetrating" power and consequently increase and help the injurious action of the bacteria.

In a word, the laity should be taught the principles of surgical cleanliness—asepsis—instead of the notion that carbolic acid is a panacea against "blood poisoning." It is still more important that the sale of carbolic acid in whatsoever form by druggists without a physician's prescription, and its prescription by physicians for patients' own use should be restricted. It is never of much use and too frequently harmful.

A CASE OF ECTOPIC GESTATION.

DIAGNOSIS AND OPERATION BEFORE RUPTURE.*

By WM. H. DUKEMAN, M.D.,

LOS ANGELES, CAL.

The patient, Mrs. J., age 28, called at my office on Monday, September 16, 1907, saying that on Saturday she was taken with pains in her lower abdomen which made her feel sick and that she had menstruated a little on that day and Sunday, but the flow had now ceased. The month before she had not menstruated and had then taken some pills to bring on her courses, which failed. She had taken nothing this month. The pulse and temperature were normal; there was tenderness over the left pelvic wall. From the character of the pains as she described them penetrating and radiating toward the heart, a diagnosis of probable tubal pregnancy was made from the above symptoms and the patient was advised to keep as quiet as possible, and if the pain should recur to go to bed at once and to call me without delay.

Three days later, about 4 P.M., she summoned me to come at once, saying that the pain had returned. Dr. Tyroler accompanied me. We found the patient in bed, looking anxious, and she gave us the following history:

The night before she had taken a dose of castor oil for constipation; about 4 o'clock in the morning she awoke with pain in the lower abdomen; her bowels moved twice, but the pain continued all day. She was flowing and had passed a good sized piece of membrane, which she was thoughtful enough to save. This was examined and found to be very much like deciduous membrane. I then made a digital examination, and found the os sufficiently dilated to admit the point of the index finger: there was tumefaction of the left pelvic cavity, giving the sensation on examination of a semi-solid mass; careful bimanual manipulation caused considerable pain over the area of the left pelvic cavity. The uterus was somewhat enlarged; the right pelvic cavity was normal.

The diagnosis was confirmed; the patient was informed of the nature of her case and that it would be necessary for her to be sent to the hospital at once. Her husband not being at home, she would not go to the hospital until she could see him. We then departed, cautioning her not to get out of bed for anything, to lie perfectly quiet on her back until her husband's return, which would be about 6 P.M., when he should 'phone me immediately. He did not call me up until the following morning, when he requested me to call at once, as his wife was no better.

On arriving at the house I informed the husband of the gravity of the case, and it was arranged to have the patient removed to the hospital for an operation without further delay. The ambulance was summoned and the patient arrived at the Good Samaritan Hospital about 10:30 A.M. The nature of the case was fully explained to the nurse and orders were given to prepare the patient very carefully for laparotomy and to administer only a low enema instead of the usual flushing. The pulse was 84, temperature 99.5°, and the patient was feeling fairly comfortable with the exception of a few slight pelvic pains occasionally. The operation was set for 1 P.M.

The nurse disregarded orders, which were to give only a low enema, and about half an hour before the operation gave the usual high enema, which aggravated the pelvic pains and undoubtedly started hemorrhage. However, the patient went on the table in good condition.

Operation was performed by myself, assisted by Dr. Tyroler; anesthesia by Dr. Magee. When the peritoneum was exposed it bulged up and was of a very purplish hue. On opening the peritoneum blood poured out. The opening was enlarged as speedily as possible and I immediately grasped the ovarian artery with my fingers and stopped further hemorrhage. About one pint of blood and clots was emptied from the abdominal cavity. The mass was then brought out of the pelvis and proved to be a tubal pregnancy of the middle and distal portion. I relaxed my grasp of the ovarian artery which showed that from the fimbriated extremities there was a slow hemorrhage. The uterine portion of the tube was normal, except slightly enlarged. There was no difficulty in extirpating the tubal mass. The ovary was not disturbed. The patient's condition continued good throughout the operation, and her recovery was uneventful.

She left the hospital at the end of two weeks, as she was anxious to return home with her two-year old boy; and at the end of one month after the operation she was again up and around attending to light household duties.

The patient has always enjoyed good health. I attended her in her confinement two years ago, when she gave birth to a healthy boy; the labor was normal.

This is the first and only case of ectopic gestation occurring in my twenty-five years of general practice.

In reviewing the symptoms I wish to say that my diagnosis of probable tubal pregnancy was based on the following points:

(1) The cessation of menstruation the month previous in a healthy woman; (2) the character of the pain penetrating and radiating toward the heart and the anxious manner in which the patient described the pain; (3) slight hemorrhage for a couple of days, accompanied by the above peculiar pelvic pains, which then ceased; (4) tenderness over the left pelvic wall.

*Presented to the Los Angeles County Medical Society and read by Dr. A. Tyroler, October 18, 1907.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, January 25, 1908.

DESTROYING FAITH IN VACCINATION.

SOME years ago, in a letter to the MEDICAL RECORD, Dr. Beverley Robinson called attention to what he called the "chief horror of smallpox." This, he said, consisted not in the loathsome features of the disease itself, but in the way the sufferers were treated by the health authorities. They are dragged from their homes and carried by force to the pest-house, enduring not only the danger of exposure during the journey, but also much distress, and not they only but those who are nearest to them. Why are they so abused? Not for their own good, but assumedly for the protection of those about them. Yet if there is anything certain in medicine it is that these others can be protected absolutely by vaccination. Which is the easier and the more humane, to take the sick man from his home and isolate him in a pest-house, or to isolate him in his own home and vaccinate all the others in the house and who may be exposed to contagion? It is an unjust and a silly practice, and one which is harmful in every way, not only not protecting those who have already been exposed, but subjecting others to the risk of contagion during the transport of the sick. It is merely a concession to a popular prejudice, and its continuance serves only to increase this prejudice and to weaken faith in the efficacy of vaccination.

The duty of the health authorities is not only to safeguard the public, but to instruct the people in matters of hygiene. The Health Department of Chicago recognizes this duty, and meets it by issuing each week a Bulletin, containing in addition to the regular health reports, various items of information regarding the diseases prevailing for the time being and little essays instructing the public as to the measures best adapted to the prevention of these diseases. Several of the State Boards of Health also publish matter of great importance in an educational sense. In the Bulletin of the Illinois State Board of Health for November and in that of the New York State Board of Health for the same month there is much of value regarding smallpox and the efficacy of vaccination. The Illinois Bulletin in particular constitutes a tract that ought to do a vast deal of good in a missionary way. It prints the second edition of a circular issued some time ago, of which 20,000 copies were distributed, showing by a number of illustrations the fearful disfigurement following an attack of smallpox in one not protected by vaccination, and even more strikingly demonstrating the absolute protection afforded infants by this simple measure. In addition to the pictures, reproduced from Welch and Schamberg's book on "Acute Contagious Diseases," there is a mass of statistical material showing the reduction in smallpox mortality in various countries following the introduction of vaccination. The New York Bulletin shows the value of compulsory vaccination and notes that, in those countries where this useful law is in force, smallpox is regarded with indifference by the people. In Japan, for example, where compulsory vaccination has been enforced since 1886, there is no provision made in any of the cities for smallpox hospitals. When a case develops the patient is allowed to stay at home or is taken to a general hospital for treatment. The disease has never been known to spread from one of these patients either in or out of hospital. The same is practically true of Germany, where vaccination and revaccination are general and no other precautions are taken to prevent the spread of the disease. In many States of this country vaccination in children is practically compulsory, as an unvaccinated child is by law prevented from attending school. As the Federal law refuses admission to unvaccinated aliens, if the school law were in existence and enforced in all the States it would be a matter of only a few years when the entire population would be protected by at least one vaccination. Unless revaccination were also practised there might be cases of varioloid and even occasionally of fatal smallpox, but there would be no danger of an epidemic, and the necessity of pest-houses, assuming that such necessity exists at present, would be done away with.

The Illinois and New York Boards of Health, as well as some other State Boards, are doing a good work in teaching the public the benefits of vaccination, and it is a great pity that the practice of some municipal boards, in trusting to imprisonment of the sick instead of protection of the well, is keeping alive the fear of the disease and weakening the belief in the efficacy of vaccination. If health officers proved their faith in vaccination by their works, and maintained smallpox hospitals for the care of the homeless sick only, the popular belief in the protective efficacy of vaccination, which at present is only half-hearted, would be immeasurably strengthened.

PHIMOSIS AND CIRCUMCISION IN INFANTS.

PHIMOSIS is nearly always present at birth and is due to a small preputial orifice as well as to adhesions between the glans and prepuce. The glans, in growing and during the erections which occur with difficult defecation in infants, gradually dilates the preputial orifice and breaks up the adhesions between glans and prepuce, a process which is usually not complete until the eighth year. In other words, a certain degree of phimosis is physiological in early childhood. Many reflex phenomena, including most of the functional diseases of childhood, have been attributed to it, and circumcision has been recommended for their cure. That the symptoms are really not caused, at least not always caused, by the phimosis is proved by the fact that in at least one-half the cases they are not relieved. In a plea for fewer uncalled-for circum-

cisions, appearing in the *Correspondenz-Blatt für Schweizer Aerzte* of December 1, 1907, G. Rheiner mentions a few of the indications and contraindications for the operation in early childhood. He considers a phimosis pathological only when it acts as a mechanical obstacle in urination. The urine is passed in a thin stream, or only a drop at a time, the space between glans and prepuce balloons out, the urine decomposes in this space, and is thus liable to cause balanitis. The straining at urination is liable to be followed by hernia or prolapsus ani, the balanitis incites to masturbation. These patients of course require circumcision if the prepuce cannot be retracted after any adhesion between it and the glans have been broken up. On the other hand, there are patients who have difficulty in urinating which is attributed to a phimosis though it is really due to other causes. Thus in cystitis and balanitis the infected urine or purulent discharge will cause an inflammation of the prepuce which renders urination painful, and this may lead to voluntary retention while there is no mechanical hindrance to the flow of urine. In such a condition circumcision, which is often advised, is really strongly contraindicated, as the wound readily becomes infected, thus aggravating the symptoms and possibly causing sepsis. In patients in whom small ulcers follow herpes preputialis similar urinary symptoms may set in, but here, too, a circumcision is contraindicated. Rheiner also draws attention to conditions which are often attributed to phimosis and in which a circumcision will do no good, though it may not cause any harm. Thus it is quite natural to attribute urinary symptoms due to a stricture (congenital or after an early urethritis) to phimosis. A more frequent source of error is the condition in which urine is passed in small quantities, its voidance being accompanied by bearing down pains. This condition exists in children troubled with constipation due to faulty diet or to fissures about the anus, and the liability to error in diagnosis is increased by the erection reflexly caused by the constipation, for during erection the small preputial orifice is more noticeable. It can readily be understood that a circumcision will not cure these patients.

In many children the physiological phimosis seldom causes any trouble, and if it does circumcision is not always necessary as one can frequently relieve the condition by retracting the prepuce after breaking up the adhesions between it and the glans. The best treatment lies in prophylaxis. We can avoid all future trouble by retracting the prepuce over the glans immediately after birth. This usually requires slight stretching of the preputial orifice, most easily accomplished by inserting a closed scissor artery forceps into the orifice and then separating the blades. Thus sufficient dilatation is brought about without causing any bleeding, after which the adhesions between glans and prepuce are broken up and the latter is easily retracted. After the removal of any smegma present, a drop of oil is placed on the glans and the skin is drawn forward. The skin should then be drawn over the glans daily until there is no longer a disposition to a recurrence of the adhesions. This little maneuver is probably not practised by many obstetricians, but it cannot be too strongly recommended, as it does no harm and may prevent much trouble.

THE WIDAL REACTION IN JAUNDICED PATIENTS.

In the past few years the reliability of the Widal reaction has frequently been questioned. Cases have been reported in which there were no signs of typhoid fever, but in which the reaction was positive in low dilutions, for example in Weil's disease, in infectious cholangitis, and in cases of fever with jaundice. Then Langstein, Joachim, and others obtained a positive Widal in higher dilutions than one in twenty, in patients in whom typhoid fever was excluded, but who suffered from diseases of the liver or gall-bladder with icterus and fever. It was suggested that the icteric serum contained substances which caused the agglutination and that these were the bile constituents, taurocholic and glycocholic acid; in fact, agglutination was brought about with the serum of an animal which had previously been injected with taurocholic acid. On the other hand, Königstein and others reported cases in which icteric blood serum had no specific action on typhoid bacilli, from which they concluded that the positive results observed by others were not due to the bile constituents but to some other agglutinins.

These different opinions led Kentzler (*Wiener klinische Wochenschrift*, October 31, 1907) to study the action of icteric serum on the typhoid, paratyphoid (A and B), and colon bacilli. He used the serum of thirty patients, twelve suffering from cholelithiasis, five from catarrhal jaundice, four from carcinoma hepatis, three from heart disease with jaundice, three from hepatitis with jaundice, one from common bile-duct obstruction, and one from Banti's disease; in none of them was there any previous history of typhoid fever. The serum of each patient was used in fifteen different dilutions, ranging from one in two to one in thirty. With the typhoid bacilli he observed a positive Widal in all the patients when low dilutions were used and a negative reaction when dilutions higher than one in twenty were employed; in only six patients was there a positive reaction with a dilution of one in twenty. With paratyphoid A bacilli no agglutination was observed with dilutions higher than one in eighteen, and only twice was the agglutination observed with dilutions higher than one in ten. With paratyphoid B bacilli agglutination was observed once with a dilution higher than one in twenty, but the same patient's serum caused no agglutination when it was diluted forty times. The coli bacilli were never agglutinated when the serum was used in dilutions higher than one in twenty, and were agglutinated by the serum of only six out of the thirty patients when it was diluted more than ten times. As control tests the serum of twelve normal individuals was used; in dilutions of one in fourteen the serum of each agglutinated the various bacilli, while agglutination was absent when higher dilutions were used.

Kentzler's observations show that sera of icteric patients do not contain specific typhoid agglutinins or agglutinins for the bacilli related to the typhoid germs. We may also conclude from his findings that when a patient's serum diluted twenty times agglutinates typhoid bacilli the patient probably has or has had typhoid fever, while if it causes agglutination in dilutions of one in forty the patient surely has or has had typhoid fever.

The Edema of Pregnancy.

Edema is a not very infrequent complication of pregnancy but in many instances its nature is rather difficult to understand. While the swelling of the lower extremities that is so common may readily be explained by assuming that the pressure of the enlarging uterus interferes with the return flow of the blood through the venous trunks the case is different when the condition involves other portions of the body or becomes general. It then seems most reasonable to regard it as the expression of a toxemia or symptom of renal inadequacy, though occasionally it is present without any evidence of gross kidney lesion. Birnbaum has found that the simple edema of pregnancy differs from that of nephritis or of the albuminuria of pregnancy in that it is not accompanied by a deficiency in chloride excretion, and he draws the conclusion that it is not the effect of a renal disorder but depends on the presence in the blood of some toxic substance. As opposed to this view is the statement of Cramer (*Münchener medizinische Wochenschrift,* December 31, 1907) that great benefit is to be derived in such cases from the rigid enforcement of a salt-free diet of the kind used so successfully in combating the fluid accumulations of nephritis. He has found that when the patients take only food prepared entirely without salt and are not allowed meat, milk, or other articles naturally rich in salts, the edema promptly subsides, only to reappear again if the dietary rule is broken. The regimen has been enforced for many weeks up to the time of delivery without any apparent prejudice to the development of the fetus. Even though the effect of this measure is difficult to explain satisfactorily it is so simple in execution and its results in adding to the patient's comfort and possibly in reducing the danger of eclampsia are so desirable that it would seem worthy of trial.

Gastrointestinal Carcinoma.

If a surgeon were asked to enumerate some of the conditions in which his art had made the greatest advances of recent years he would probably include in the number the malignant new growths of the stomach and intestine. It is also likely that much of the progress made would be attributed to the fact that it is now possible to diagnosticate these tumors earlier and that the patients reach the operator sooner than was formerly the case. While these statements are hardly subject to controversy, Boas, whose experience in this field is, as well known, very wide, says (*Deutsche medizinische Wochenschrift*, January 2, 1908) that the matter of the benefits of early operation is not quite as simple as at first sight it appears. Actually there are great variations in the malignancy of gastrointestinal neoplasms, so that in a case in which the disease has progressed so slowly that a considerable length of time has elapsed before a positive diagnosis can be made the operative prognosis is really more favorable than if the cancer had been of so actively growing a type as to indicate operation within a few weeks or months of the first onset of symptoms. In support of this contention he quotes the statistics of several operators, for example those of Makkas who found that of seventeen patients who had remained free from recurrence for three years, only three had been operated on within two to three and a half months of the first symptoms, while in the other fourteen cases symptoms had been present for from five months to two years. Hoffman of the Breslau clinic has stated that the optimum for resection is found at a period between six and twelve months after the first onset of symptoms, and Nordmann of Körte's clinic, after a very careful study of recorded cases and a comparision of the results of operations performed at varying stages in the course of the disease, has come to practically the same conclusion. According to Boas these circumstances do not indicate that any reduction of surgical activity is desirable but rather that the mere fact that the patient reaches the operator late is not of itself a contraindication to laparotomy, and they furthermore emphasize the necessity for greater efforts in the early diagnosis of the doubtful cases and in the careful selection of those to be subjected to exploratory operation.

An Improvement in Blood-culture Technique.

Among the laboratory aids to diagnosis none is, at certain times and under certain circumstances, of greater value than the bacterioscopic examination of blood-cultures. At the same time, none is perhaps more difficult and more troublesome to carry out properly. In order to carry out the examination satisfactorily several cultures must be made in different media, and this calls for a display of apparatus that is often alarming to the patient as well as inconvenient to the bacteriologist. The rapid coagulation of the blood not only necessitates quick work, but also at times retards or prevents the growth of the bacteria through its property of increasing the bactericidal action of the serum. A method of preventing coagulation is, therefore, a desideratum in blood-culture technique. Albert A. Epstein, writing in the *American Journal of the Medical Sciences* for September, suggests for this purpose a solution of 2 parts of ammonium oxalate and 6 parts of sodium chloride in 1,000 parts of distilled water. This solution is practically isotonic with blood, and exerts no restraining influence on bacterial growth. To the blood drawn from the vein an equal amount of this sterilized solution is added, and the two are thoroughly mixed. The test-tube can then be taken to the laboratory, where the cultures can be prepared in any way desired. Epstein has compared cultures made from this mixture with controls made from undiluted blood, and has found the results identical. In addition to the ease with which blood-cultures can be taken by this method, he says, it offers other advantages. The oxalated blood may be centrifugalized, and spreads may be made from the sediment and examined microscopically for bacteria. In many cases in which there is an intense infection an early diagnosis can be made by means of this technique. The supernatant fluid which remains after the centrifugalization has been completed can be employed for the determination of the opsonic index of the blood.

Telephone Otitis.

No one who has witnessed the nerve racking activities of the professional telephone operator can wonder at the occasional occurrence among these workers of nervous or other troubles that are attributable to their employment. Indeed it is rather a matter of astonishment that this result does not more often follow, and it is even stated that the functional capacity of the ear is improved rather than impaired. A somewhat unusual instance of disease referable to the habitual use of the telephone is reported by Hamm (*Berliner klinische Wochenschrift,* December 30, 1907) in which an inflammatory process of the external ear was caused. The patient was a postoffice official who was obliged to transact a large amount of business daily by means of the telephone. He came to the author with the statement that for over a year he had been suffering from increasing pain and tenderness and deafness in the left ear which had compelled him to use the right in telephoning, until now this was also affected in the same way. The diagnosis of fetid, diffuse external otitis was made and it was found that improvement promptly attended non use of the telephone only to be followed by a relapse when an attempt was made to resume the regular routine. The author believes that the malady was caused by the continued action of electrical currents escaping from the receiver when held to the ear, and quotes the opinion of Professor Peukert, a technologist to whom the case was submitted, to the effect that measurements show that the act of telephoning is regularly accompanied by the passage into the body of currents which by cumulative action are capable of inducing organic lesions.

Treatment of Hay Fever.

The treatment of this disease may be divided into that during the attack and that in the interval. In the interval pathological nasal conditions may be operated upon or the sensitive areas of mucous membrane may be destroyed; and, since in many instances a form of chronic neurosis exists, remedies which improve the stability of the nervous system may be employed. During the attack the patient should go to a climate free from the source of irritation, but, as this is often impossible, palliative remedies are employed at home which tend to render the mucosa less sensitive to the irritant. Most of these are at best uncertain and but partially successful, and many are notoriously useless. As is always the case with a malady so difficult to cure, the multitude of methods which have been suggested gives sufficient evidence of failure, but every now and then some new form of treatment is described which has benefited some one. In the *Correspondenz-Blatt für Schweizer Aerzte* for August 1, 1907, Hürlimann refers to two patients on whom he successfully tried dry, hot air. A basket containing six electric light lamps was placed over the patient's face, while his forehead and eyes were covered with a cold, damp cloth; a woolen cloth was thrown over the basket in order to retain the heat, an opening being made on one side to permit fresh air to enter. The patients were told to breathe in through the nose and to expire the air through the mouth. After thirty inspirations the basket was removed, though Hürlimann believes the number could be increased without any discomfort to the patient. This method is simple enough and so readily carried out as to be deserving of trial by sufferers.

News of the Week.

Physicians for the Canal Zone.—The United States Civil Service Commission announces an examination on February 19-20, 1908, to secure eligibles from which to make certification to fill vacancies as they may occur in the position of physician, at $150 per month, in the Panama Canal Service. It is probable that about fifteen appointments will be made, this estimate being based upon the number of appointments made during the past year. Applicants must be men between the ages of twenty and forty-five years, and must indicate in their applications that they are citizens of the United States, graduates of recognized medical schools, and have had at least one year's experience as interne in a general hospital. Persons lacking the above qualifications will not be admitted to the examination. Special credit will be given to physicians who show that they have been for more than a year members of the house staff of large metropolitan hospitals. Persons appointed to positions under the Isthmian Canal Commission will be expected to proceed promptly to the Isthmus. Persons examined for positions under that Commission will not be eligible, as the result of such examination, to positions in the United States and Philippine service. Applicants should apply to the United States Civil Service Commission, Washington, D. C., for application Form 1312. No application will be accepted unless properly executed and filed with the Commission at Washington prior to the hour of closing business on February 10, 1908.

Civil Service Examinations.—The State Civil Service Commission will hold examinations February 15, 1908, for the following positions: Physician, State Hospitals, $900 and maintenance; Trained Nurse, State Institutions, $420 to $600 and maintenance. The last day for filing applications for these examinations is February 8. Full information and application forms may be obtained by addressing Charles S. Fowler, the Chief Examiner of the Commission at Albany.

Anti-tuberculosis Headquarters in Albany.—Homer Folks, Secretary of the State Charities Aid Association, with a force of investigators and clerical assistants has opened permanent headquarters in Albany for the promotion of a campaign against tuberculosis in the fifty-seven counties outside of Greater New York. The establishment of this bureau has been made possible by the donation of a large sum by a benefactor whose name is to be withheld as one of the conditions of the gift.

Physicians to Instruct Lawyers.—Medical instruction is to be given trial attorneys in Chicago, connected with the office of Corporation Counsel Brundage, in order to protect the city from damage judgments and personal injury cases.

Illinois Cocaine Bill Now a Law.—Gov. Deneen has signed what is known as the cocaine bill, which was passed by the present session of the Legislature. The measure is intended to regulate the sale of cocaine, and heavy penalties are provided for violation.

Diseases of Occupation.—Gov. Deneen, of Illinois appointed the following commission, authorized by the General Assembly to investigate the diseases of occupation in the State and report to the next General Assembly: Dr. L. Hektoen, of Chicago; Dr. Alice Hamilton, of Hull House, Chicago; Dr. George W. Webster, of Chicago, President of

the State Board of Health, and the Secretary of the State Board of Health, Dr. James A. Egan.

Pure Food Commission.—The President has decided to appoint a Pure Food Commission of chemists from various universities, to consider cases of dispute against the rulings of the Department of Agriculture.

Charitable Bequests.—By the will of the late Alexander Crawford, of Philadelphia, the sum of $2,300 is bequeathed to the Northern Dispensary, and $1,000 to the Sheltering Arms. In the event of a nephew, who is the principal beneficiary under the will, leaving no issue, the Episcopal Hospital is to receive $10,000 for the endowment of a free bed as a memorial to the testator's wife, the Northern Dispensary an additional $3,000 and the Sheltering Arms an additional $2,000.

Extreme Heat in Australia.—Despatches from Melbourne, state that a heat wave of unusual intensity is causing great suffering throughout Victoria. The theaters have been compelled to close, the people are sleeping out of doors and thirty-two deaths from sunstroke have been reported in a few days.

Measles in Pennsylvania.—According to the record of the State Department of Health during 1906, there were 1,463 deaths from this disease in Pennsylvania, 1,240 of the number being of children under five years of age. In December alone 2,307 cases were reported.

Ambulance Accident.—An ambulance of the Brooklyn Hospital was struck by a trolley car at Lawrence and Willoughby Streets on Sunday evening. The ambulance was wrecked and the driver and surgeon were thrown to the ground, the former receiving internal injuries and fractures of several ribs, while the latter, Dr. Albert F. Anderson, fractured his shoulder and several ribs.

Summer Diarrhea of Infants.—Dr. James L. Walsh, of 1719 Third Street, Bay City, Mich., desires to get reports of cases in which physicians have used the method of infant feeding, suggested in his article published in the MEDICAL RECORD, September 15, 1906.

Harvey Society Lectures.—The fifth lecture in the Harvey Society course will be delivered by Prof. George W. Crile, of the Western Reserve University, at the Academy of Medicine, on Saturday, January 25, at 8:30 P.M. Subject: "Shock." All interested are cordially invited to be present.

Carnegie Institute.—At a meeting of the Carnegie Institute, Pittsburg, January 2, the questions of reducing the period of collegiate and medical study from eight years to six, and of promoting reciprocity in State medical examinations were discussed.

Opium in China.—The Chinese government has extended by another three months the period during which all officials must abandon the opium habit under penalty of losing office and other punishments.

Banquet in Honor of Dr. Lucy Waite.—A banquet in honor of Dr. Lucy Waite, of Chicago, was held in Denver, Col., on January 1.

Woman Ambulance Surgeon in Brooklyn.—Dr. Mary M. Crawford, of the Williamsburg Hospital, is said to be the first woman to have occupied the post of ambulance surgeon in Brooklyn.

Dr. J. C. Biddle has resigned as surgeon in chief and superintendent of the State Miners' Hospital, at Fountain Springs, Pa.

A Memorial to Brehmer.—At the Twenty-ninth Balneological Congress, which convenes in Breslau on March 5, a monument in honor of Herman Brehmer, a pioneer in the sanatorium treatment of tuberculosis is to be unveiled.

Dr. Theobald Smith, professor of comparative pathology at Harvard University, has been given the degree of LL.D., by the University of Chicago.

A New Nose and Throat Journal.—Under the title *Beitrage zur Anatomie, Physiologie, Pathologie und Therapie des Ohres, der Nase und des Kehlkopfes,* a new journal devoted to diseases of the ear, nose and throat, is to be published by the firm of S. Karger, Berlin, Karlstrasse 15, under the editorship of Professor A. Passow and Prof. K. L. Schaefer.

Honors for the Late Dr. Senn.—Dr. Senn, just before his death, on January 2, had received the Order of Merit of the Japanese Society of the Red Cross, and had also been elected an honorary member of the Royal Medical Society of Budapest.

The Hospital Conference of the City of New York.—The next regular meeting will be held on Wednesday, January 29, at 8:15 P.M., at the Academy of Medicine. The program will include a consideration of the report on the future hospital needs of Greater New York, presented for endorsement by the hospital committee of the State Charities Aid Association, and the discussion of experiences in the purchase of food supplies.

Freemont County (Col.) Medical Society.—At its meeting, held in Florence, on January 8, this society elected the following officers: *President,* Dr. C. H. Graves, of Canon City; *Vice-President,* Dr. W. R. Williamson, of Rockvale; *Secretary-Treasurer,* Dr. R. C. Adkinson, of Florence.

Gage County (Neb.) Medical Society.—This society held its fifth annual meeting in Beatrice, on January 9, and elected the following officers: *President,* Dr. F. E. Osborne; *Vice-President,* Dr. C. S. Curry; *Secretary-Treasurer,* Dr. J. I. McGirr.

Washington County (R. I.) Medical Society.—At the meeting of this society, held in Providence on January 10, officers were elected as follows: *President,* Dr. F. I. Payne; *Vice-Presidents,* Dr. M. H. Scanlon and Dr. Horace Wilcox; *Secretary-Treasurer,* Dr. J. H. Morgan.

Tuscaloosa County (Ala.) Medical Society.—The election of officers of this society at the annual meeting, held in Tuscaloosa, on January 8, resulted as follows: *President,* Dr. W. G. Sommerville; *Vice-President,* Dr. J. A. Lanford; *Secretary-Treasurer,* Dr. J. H. Ware.

Rhode Island Homeopathic Medical Society.—This society held its annual meeting in Providence on January 10, and elected the following officers: *President,* Dr. George F. Allison; *Vice-President,* Dr. Arthur H. Wood; *Secretary,* Dr. Jeannie O. Arnold; *Treasurer,* Dr. Dudley A. Williams; all of Providence.

Morgan County (Ala.) Medical Society.—At a meeting of this society, held in Decatur on January 4, the following officers were elected: *President,* Dr. C. S. Shenault; *Vice-President,* Dr. H. C. McRee, of Hartselle; *Secretary-Treasurer,* Dr. J. L. Gunter.

Phillips County (Ark.) Medical Society.—At the meeting of this society, held in Helena, on

January 10, officers were elected as follows: *President,* Dr. M. Fink; *Vice-President,* Dr. J. W. Bean; *Secretary and Treasurer,* Dr. W. C. King.

Annex to St. Joseph's Deaf and Dumb Institute.—Work will be begun next month on an annex to be erected at a cost of $250,000, by St. Joseph's Deaf and Dumb Institute on its plot at the northwest corner of 188th Street and Bathgate Avenue, The Bronx.

Morgan County, Illinois, Medical Society Library.—This society has established at Jacksonville, a medical library for the use of its members, comprising over 1,700 volumes and provided with current files of the most important medical periodicals in the English language.

Philadelphia Medical Club.—At the annual meeting, held January 18, the following officers were elected for the ensuing year: *President,* Dr. George McClellan; *Vice-President,* Dr. Wharton Sinkler, Dr. James B. Walker; *Secretary,* Dr. J. Gurney Taylor; *Treasurer,* Dr. Lewis H. Adler, Jr.; *Governor,* Dr. Oscar H. Allis; *Additional Directors,* Doctors M. B. Hartzell, Walter L. Pyle, H. H. Whitcomb, Albert M. Eaton, Wilmer R. Krusen.

Philadelphia County Medical Society.—At a stated meeting, held January 15, the following were elected officers for the ensuing year: *President,* Dr. Albert M. Eaton; *Vice-presidents,* Dr. Henry W. Cattell, Dr. Frank C. Hammond, Dr. William Evans, Dr. Robert L. Pitfield, Dr. Henry G. Godfrey, Dr. John B. Turner; *Secretary,* Dr. William S. Wray; *Assistant Secretary,* Dr. Alexander R. Craig; *Treasurer,* Dr. Collier L. Bower; *Censor,* Dr. William M. Welch; *District Censor,* Dr. M. B. Hartzell.

Hartford (Conn.) Medical Society.—At the meeting of this society held on January 6 the election of officers resulted as follows: *President,* Dr. Frederick S. Crossfield; *Vice-President,* Dr. P. H. Ingalls; *Secretary,* Dr. W. H. Van Strander; *Assistant Secretary,* Dr. Orin R. Witer; *Treasurer,* Dr. George K. Welch; *Librarian,* Dr. Walter R. Steiner.

Meeting of Osteopathic Society.—The first midyear meeting of the New York Osteopathic Society was held at the Hotel Knickerbocker, New York City, on January 18.

Aiken County (S. C.) Medical Society.—At the meeting of this society, held in Aiken on January 8, the following officers were elected: *President,* Dr. A. Holsonbake, of Graniteville; *Vice-President,* Dr. C. A. Teague, of Graniteville; *Secretary and Treasurer,* Dr. Harry H. Wyman.

Obituary Notes.—Dr. Edward Buncombe Goelet, of Saluda, N. C., died suddenly on January 19, at the residence of his daughter in Brooklyn, N. Y. The cause of his death was acute cardiac dilatation. He was a brother of Dr. Augustin H. Goelet, of this city. Dr. Goelet was born in 1843 and was a graduate of Tulane University. He was a member of the Buncombe County, N. C., Medical Society, of the North Carolina Medical Society, and of the American Medical Association. He was also a prominent Mason, connected with the lodge at Asheville, N. C.

Dr. Joaquin Morill, of Poughkeepsie, N. Y., died of tuberculosis on January 14, at the age of sixty-seven years. He was born in Havana and was graduated from the University of Havana in 1860. He came to this country in 1861 and served as surgeon in the Civil War, being captured and confined for a long time in Libby Prison. Since 1874 he lived in Poughkeepsie.

Dr. Charles M. Klock, of St. Johnsville, N. Y., died on January 17 at the age of fifty years. He was a native of St. Johnsville and was graduated from the New York University Medical School in 1876.

Dr. Joseph Coffey, of this city, died suddenly of heart disease on January 17, at the age of forty-seven years. He was born in England, and at one time had been the physician to the Tombs Prison.

Dr. Adrian T. Woodward, of Brandon, Vt., died on January 9, at the age of eighty-nine years. Dr. Woodward was born in Castleton and was the son of Dr. Theodore Woodward, who was one of the founders of the Castleton Medical College. He was graduated in medicine from that institution in 1847 and began practice in Whitehall, N. Y. In 1851 he returned to Castleton and nine years later moved to Brandon. He served through the Civil War as surgeon of the 14th Vermont Volunteers and later held a position on the faculty of the medical department of the University of Vermont, resigning in 1890 on account of failing health. He had held the presidency of the Vermont State Medical Society and of the Rutland County Medical Society.

Dr. J. P. Gale, of Berkeley, Cal., died suddenly of heart disease on January 4, at the age of fifty-four years. He was a native of Missouri but had practised for nineteen years in Arbuckle, Cal., before removing to Berkeley a few months ago.

Dr. A. Curtiss, of Big Rapids, Mich., died on January 10 of apoplexy, at the age of sixty-four years. Dr. Curtiss was a veteran of the Civil War and came to Big Rapids in 1882.

Dr. Charles H. Taylor, of South Bend, Ind., died of pneumonia on January 8, at the age of thirty-nine years. He was a graduate of Indiana University and Rush Medical College.

Dr. Stephen H. Murphy, of Chelsea, Mass., died on January 13, at the age of thirty-five years. He was born in Salem and was graduated from Boston College and the Harvard Medical School.

Dr. Frederick S. Thomas, of Charleston, W. Va., died of pneumonia on January 7, at the age of fifty-seven years. Dr. Thomas was born near Charleston, and in 1880 was graduated from the medical department of the University of Maryland. He practised for a time in Malden, W. Va., and in 1884 removed to Charleston.

Dr. Thomas H. Craven, of Canon City, Col., died on January 3, at the age of seventy years. He was born in Missouri, and after serving in the Civil War settled in Gilpin County, Col., removing to Canon City in 1869.

Dr. Jared Y. Dale, died at Lemont, Pa., of paralysis, on January 14, at the age of sixty-six years. He was graduated from the medical department of the University of Pennsylvania in the class of 1863. He was secretary of the Center County Medical Society.

Dr. Frank R. Brunner, of Eshbach, Pa., was burned to death in the disastrous fire of Boyertown, on January 13. He was seventy-three years old and was graduated from Jefferson Medical College in the class of 1861. He was a member of the Pennsylvania Senate in 1885.

Dr. Emil Maurer, died at Philadelphia on January 17, at the age of forty-one years. He was graduated from the Medico-Chirurgical College of Philadelphia in the class of 1898.

Correspondence.

THE ANTIVIVISECTION BILL.

To the Editor of the Medical Record:

Sir:—On April 8, 1907, the president of the Medical Society of the State of New York appointed twenty four members thereof to be a "Committee on Experimental Medicine," in view of proposed legislation calculated to injure the progress of medicine by restricting experimentation. As agitation in this direction has recently been renewed, in a very plausible form, the undersigned have been instructed by the said committee to send you the following copy of a preamble and resolution adopted at a meeting held in New York City, on January 15, 1908, and respectfully to request the publication thereof in the Medical Record:

Whereas, In the State of New York a petition is being widely circulated among medical men for signature in favor of a proposed bill entitled "An act to prevent cruelty by regulating experiments on living animals;" and

Whereas, The said bill contains in its provisions conditions which would probably seriously impair the progress of scientific medicine,

Resolved, That the Committee on Experimental Medicine of the Medical Society of the State of New York earnestly requests the members of the medical profession to refrain from signing the aforesaid petition, and urges any who may have signed the same by inadvertence to withdraw their signatures.

The present laws of this State relating to this subject have long proved adequate and satisfactory.

Joseph D. Bryant, M.D., Chairman
John G. Curtis, M.D., Secretary.

OUR LONDON LETTER.

(From Our Special Correspondent.)

HEALTH OF LONDON—ROYAL SOCIETY OF MEDICINE SECTIONS—CLINICAL EXHIBITS—GASTRECTOMY, A COMPLETE CASE—CHLOECYSTECTOMY—OBITUARY, SIR A. GARROD.

London, January 3, 1908.

The report of the Medical Officer of Health for the county of London (Sir S. F. Murphy) for 1906 has just been issued. The death rate remained at 15.1 per 1,000, as in 1905, and is the lowest recorded up to then. The marriage rate was 17.1, not much above the previous year, when the lowest was recorded. The birth rate (26.5) was the lowest ever recorded. The death rate from epidemic diseases was 1.93 per 1,000 persons living, a little above the previous year's rate. Diphtheria, scarlet fever, and measles showed a slight increase, enteric fever a decrease.

The control of tuberculosis is discussed at length by the Medical Officer of Health, the question of putting in operation the recent act being under the consideration of the Public Health Committee. With reference to the medical inspection of school children, there is raised a question as to whether it is of much benefit unless treatment be superadded, and we are told that sooner or later school clinics will have to be established for the commonest disorders, such as eye, ear, and skin troubles.

The clinical section of the Royal Society of Medicine has had an exhibition of cases of a various and interesting kind. They were, however, too numerous to catalogue in a letter and I will content myself with mentioning some. There was one with a large ulcer on each leg, dressed daily for thirty years with carbolic oil (1 in 20). Six years ago the ears and whites of eyes began to turn black, and two years ago the urine to be dark. The skin of face and exposed parts became dusky. By rest in bed the ulcers diminished in size and the staining did not increase, though the dressing was continued. This was said to be the second case in England of ochronosis, as described by Bostvoen.

A case of splenic polycythemia, presenting in an unusual degree the three features of the disease, was shown by Prof. Osler.

Mr. Openshaw showed a case of traumatic dislocation of the hip with fracture of the femor of thirteen months' duration which he had reduced by manipulation. The actual shortening on admission was 3 3-4 inches. This was reduced to 1 1-2, due to overlapping of the fragments of the femor.

Dr. Essex Wynter showed a case of methemoglobinemia of twelve years duration in a woman of forty-five. It was at first thought to be Addison's disease. She had general yellowish pallor, with a lilac tinge of mucous membranes, weakness, constipation, and occasional vomiting. Temperature was 100 F. Pulse 74 to 96. A pulmonary systolic brut was noticed. There was some discussion on this case and a committee was appointed to report on it.

Dr. Wynter also showed a girl of fifteen months with amyotonia (congenital). The flabbiness of muscles and freedom of joint movements were remarkable. The toes could be made to touch the front of the leg or the fingers the back of the forearm, and the legs could be flexed to the chin. The muscles did not contract on strong Faradism and moderate currents did not seem to be painful.

Another case brought forward by Dr. Wynter was of ascites cured by a novel plan, viz., drainage into the subcutaneous tissue outside the abdomen so as to obviate repeated tapping and yet let the patient get about. The operation was done by Mr. Sampson Handley on September 23, and by November 20 there was no fluid in the abdomen and the patient has walked about since. The incision was made as for femoral hernia, and with one finger in the abdominal cavity a process of peritoneum drawn down, split, and the edges stitched right and left to maintain the opening. There was a little oozing from a stitch puncture in the thigh for about three weeks, but this showed the communication remained open. No hernia followed and no edema of the thigh, the girth of which was rather less than that of its fellow.

In the surgical section, Mr. B. G. A. Moynihan of Leeds related his second case of complete gastrectomy, and brought the patient, who seemed to be in good health and said he could eat almost anything now, but must eat slowly. He was said to have gained two stones in weight since the operation, on May 24 last. The man is forty-three years old, and two years ago first began to suffer from pain after his food, which was relieved by vomiting, until he again ate something. Dieting, lavage, and other treatment helped him for a time; but he noticed that the pain came on sooner after meals and he lost weight, so that when admitted to the infirmary he was greatly emaciated and could only swallow fluids, and these by teaspoonfuls. The stomach was washed out, but pain and distress came on as soon as about four ounces of fluid was introduced. It was soon returned clear, once with a little blood and several times some bile. Only about two-thirds of the amount introduced returned. A stomach tube passed seventeen inches easily, but no further. Inflation produced a puffy swelling the size of a billiard ball in the left upper half of the epigastrium just below the costal margin, definitely circumscribed, and no other swelling. The diagnosis thus pointed to was probably hour-glass stomach from cicatricial contraction of an ulcer on the lower curvature and close to the cardia. The possibility of its being an example of "leather-bottle stomach" (linitis plastica of Brinton) was pointed out to the class, and at the operation this was found to be the case. The organ felt solid, with thick walls and an insignificant cavity, larger at the cardiac end and something like a Florence flask. Gastrotomy was obviously impossible, and Mr. Moynihan proceeded to remove the whole stomach. He described the operation at length. The most difficult part was the anastomosis of the esophagus to the jejunum, which was facilitated by flexing the patient's neck as much as possible and traction on the esophagus, which brought three-quarters of an inch below the diaphragm. The patient bore the operation well and convalescence was uninterrupted. A point Mr. Moynihan mentioned as important will be observed by future operators. Finding the stomach pendulous from the esophagus, he realized that it would, with the greatest advantage, hold the tube in a fixed position until his suture lines were complete, thus solving one of the greatest difficulties of complete gastrectomy and perhaps furnishing a principle applicable to other operations.

The specimen was examined by Dr. Craven Moore. it measured 4 1-2 inches in length, was tubular, divided into a globular smaller cardiac end, passing by a narrow constriction into the greatly contracted pyloric portion. Under the microscope its appearance was that of atrophic scirrhus.

Mr. McAdam Eccles gave particulars of a similar case in a woman of forty-six in whom he had done an almost complete gastrectomy. He was able to

make a junction between the esophagus and the duodenum, as this was very mobile. The patient survived for eleven months, but then died from secondary deposits in the liver, he thought, but could not obtain a post mortem. The microscopical examination of the specimen very closely resembled that in Mr. Moynihan's case.

Another paper in this section was read by Mr. J. D. Malcolm. It was on cholecystectomy. He had had seven cases, and the after history was so good that he thought it might be performed oftener with advantage. He admitted that the danger of new gallstones forming after complete emptying was slight, but he thought the more severe operation was not to be rejected, and when disorganization of the gall-bladder was extreme excision was necessary.

Mr. Moynihan, commenting on the paper, said he excised less often than formerly. The condition of the patient and other difficulties interfered to prevent excision becoming a routine procedure. The most experienced surgeon might not be able to exclude with certainty abnormal conditions of the common duct and ampulla.

Sir Alfred B. Garrod, F.R.S., died on Saturday in his eighty-ninth year. Educated at Ipswich grammar school and University College and Hospital, he graduated at the London University, taking first place at the M.B. (1842), and again at the M.D. the next year. In 1847 he was appointed to a vacancy on the staff of his hospital as assistant physician, and in 1851 professor of therapeutics in the college. Then he joined the College of Physicians, of which he was elected a Fellow in 1856. Later on he migrated to Kings College as professor of therapeutics and physician to the hospital to which he became consulting physician on his retirement some years ago. He has served as senior censor at the College of Physicians and as vice-president twice. He delivered the Goulstonian Lectures there in 1858 on diabetes and the Lumleian lectures in 1883 on urine and renal calculi. The Moxon gold medal for researches in clinical medicine was awarded to him in 1891. His manual of materia medica and therapeutics was for many years the favorite textbook of London students. His principal clinical work was done in relation to gout and rheumatism, the formation of uric acid in the body, and the value of certain remedies in gouty and rheumatic conditions, *e.g.* guaiacum and lithia, the last of which he first introduced into practice. His Knighthood was conferred at Queen Victoria's Jubilee, 1887, and he was soon after made one of Her Majesty's physicians extraordinary.

OUR VIENNA LETTER.

(From Our Special Correspondent

INTESTINAL OBSTRUCTION SECONDARY TO EPIDIDYMITIS—SUTURE OF THE HEART—PLASTIC OPERATION ON THE ULNA—INTESTINAL PERFORATION DUE TO ASCARIS—DISEASE OF THE RETINAL VESSELS—EXCISION OF THE LARYNX AND ESOPHAGUS—BRONCHOSCOPY.

VIENNA, December 22, 1907.

BALAS has operated on a case of intestinal obstruction which developed as a complication in a gonorrheal epididymitis. The patient was a smith, twenty-eight years old, who manifested symptoms of intestinal occlusion in the fourth week of the epididymitis. Four days later he was admitted into the hospital and at the laparotomy a loop of intestine was found adherent to the edge of the pelvis along the course of the vas deferens. This was angulated in such a way as to prevent the passage of intestinal contents, but the loop was freed from its attachment without great difficulty and the lumen restored. Peritonitis was already present, however, and the patient died twenty-four hours later. The autopsy and the results of the bacteriological examination showed that the gonorrheal process had involved the vas and that through perforation of this structure a subperitoneal abscess had formed. This occasioned a local peritonitis, causing adhesions and finally intestinal obstruction, which in turn gave rise to the general peritonitis.

Luksch of Graz operated on a boy of thirteen years who had received a gunshot wound of the heart, which was successfully treated by suture. The projectile was 6 mm. in diameter and had entered in the fourth intercostal space between the left sternal border and nipple. There was slight external hemorrhage, the patient was semiconscious, restless, and anemic, with a pulse of 140 and barely palpable. The cardiac dullness was increased upward and the sounds were not audible. At the left base there was dullness to the angle of the scapula. The operation was performed two and a half hours after the injury. The projectile had pierced the left ventricle, from which the blood streamed at each systole. The wounds of entrance and exit were closed with sutures of iodine catgut, the heart coming to a standstill during the procedure and then beating regularly again. The pleura and pericardium were closed with catgut sutures. The wound healed without reaction and the patient was out of bed on the fourteenth day. During the third week a cerebral embolus caused left-sided paralysis, but this has since subsided completely. In a radiograph the projectile could be seen lying to the left of the vertebral column.

Moriz Chudovszky successfully replaced a large portion of the ulna removed at operation. The patient was a man of twenty-six, who had noticed a swelling of his left forearm, which had progressed during three years. On admission a swelling was seen occupying the upper and middle third of the ulnar side of the forearm, fusiform in shape, and in part of bony hardness, in part cartilaginous. The growth was attached to the ulna, but the muscles were somewhat movable over it. The skin was freely movable; there was no pain. The largest circumference of the forearm was 34 cm. At the operation the growth was removed and a piece of boiled beef fibula 14 cm. long, 1 cm. wide, 4-5 mm. thick was placed in the gap. Holes were bored in the stumps of the bone and the ends of the graft placed in these. The wound was closed in layers and a firm dressing was applied. The growth was an osteochondrosarcoma, the resected portion being 10 cm. in length. The wound healed without complications, the fixation dressing being kept in place for twenty-one days. Now, six months later, the man is able to work and the radiograph shows that the implanted piece is but little thinner than the ulna.

Franz Orsos has reported a case of intestinal perforation due to the ascaris. The patient was a man of forty-four, who came into the hospital at night with symptoms of incarcerated hernia. An attempt at operation resulted in the evacuation of an abundance of pus; the next morning he died. At the autopsy a general purulent peritonitis was found and there was a perforation the size of a bean in one of the loops of the ileum. Under the transverse colon there was a dead male *Ascaris lumbricoides* 12 cm. in length. The perforation with its consequences had been caused by this parasite, which was lying free in the abdominal cavity. The situation and nature of the perforation, the normal condition of the mucous membrane in the rest of the intestine, and the changes about the colon caused by the worm and showing that it is able to penetrate the intestinal wall all indicated that the injury had been caused by the parasite alone. It first penetrated the mucosa and then burrowed under the peritoneum until this finally tore also. A striking proof of the ability of the worm to perforate the gut was presented by the conditions existing at the place where the worm was lying; here the peritoneum had been lifted up and the head of the worm was under it. The parasite had first caused an abscess and had then crawled up to the omentum, its path being indicated by the abscess passages communicating with the main cavity and leading up to the omentum.

Goldzieher observed a case of disease of both the artery and central vein of the retina giving the clinical picture of arterial obstruction and venous thrombosis. The patient was an old woman with severe nephritis manifested by a large amount of albumin with many pus cells, red blood cells, degenerated epithelial cells, and casts in the urine. There was cardiac hypertrophy. The patient said that early in January she noticed a diminution in visual power accompanied by severe headache. The right lens was transparent, but on the anterior surface there were several blackish deposits and there were many fine flocculi in the vitreous body. The outlines of the optic disc were obliterated and pale; the arteries being replaced by white bloodless striæ. The lumen of the veins had also disappeared and there remained only delicate red markings. In the macular region a cherry red spot was visible surrounded by a white area and there were many fresh hemorrhages with white areas scattered over the entire retina. The eye was perfectly blind while the left eye was perfectly healthy. This condition can be explained on the basis of there being two processes; there was thrombosis of the central vein causing a hemorrhagic retinitis and then complete obliteration of the central artery was caused by a proliferating endarteritis which led to blindness.

Hertle has operated on a woman from whom he removed the larynx and a portion of the esophagus for a carcinoma of the latter structure involving the larynx. The trachea and the distal stump of the esophagus were sutured to the skin above the jugulum and the pharynx was completely closed. Before the operation a gastrostomy was done in order to secure the patient's nutrition. A flap of the skin of the neck was introduced in the position of the resected portion of the esophagus in order to make it possible to replace this organ by suturing this flap into a tube at a later operation. The patient is able even at present to take food by mouth through the intervention of a rubber tube connecting the pharynx and esophagus.

Marschik removed a foreign body from the right main bronchus of a boy of five years by means of the bronchoscope. The boy had inhaled a fish bone, the accident being followed by sudden aphonia and pain on swallowing, but no asphyxia. The laryngoscope showed that the foreign body was wedged in the subglottic space exactly in the midline between the vocal cords. In partial anesthesia Marschik attempted to remove the fish bone with laryngeal forceps, waiting for a moment when the glottis opened. The object was successfully seized, but at the moment of withdrawal the child gave a struggle and the bone slipped from the instrument. A bronchoscope tube with an internal diameter of 6 mm. was then introduced and the end of the foreign body could be seen in the right main bronchus. It was grasped with a bronchoscopic forceps and readily extracted at the first attempt. In spite of this success Marschik is of the opinion that tracheotomy is a more reliable procedure since bronchoscopy if prolonged involves danger of edema of the glottis which would require tracheotomy.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

THE ANTHRAX SITUATION—SERUM TREATMENT OF MALARIA—DIPHTHERIA—MEASLES—CHOLERA.

MANILA, P. I., November 23, 1907.

THE regular monthly meeting of the Manila Medical Society took place at St. Paul's Hospital at 8.30 P.M., November 11. Owing to the wide publicity given in the newspapers with regard to the quarantine of certain vessels which brought anthrax cattle to Manila from the port of Hongkong, it was deemed desirable to discuss the anthrax situation before the Society. Dr. Nesom, Director of Agriculture, opened the discussion upon animal anthrax, and stated that when this disease was once introduced into a country, it was practically impossible to eradicate it; and that the losses might reach the same proportions as those which have caused such great havoc in the Philippines heretofore on account of rinderpest; and since anthrax is not prevalent at the present time in the Philippine Islands, it is most important that no importations of same should take place. The case in question arrived upon the steamship *Loonsang* November 2. One of the animals had just died and the post mortem revealed lesions suspicious of anthrax. Microscopical examination showed a bacillus closely resembling that of anthrax. This was cultivated and later positively identified as the anthrax bacillus. The entire shipment of cattle was deported to Hongkong.

Dr. Heiser, Director of Health, discussed human anthrax, and stated that from an epidemiological or public health standpoint, the disease was not of great importance because it did not show a great tendency to spread, and was only conveyed by direct contact. For instance, in Great Britain, where the disease was prevalent, from time to time, among wool sorters and others, no more than 40 or 50 cases had been reported per annum, and when the necessary precautions were taken in disinfecting wool and hides, the disease rapidly disappeared. He stated that several cases of human anthrax had been reported in the Islands, but the points at which they were said to have occurred were so remote that they were not microscopically confirmed. He stated that the eradication of the disease from seagoing vessels was a most difficult matter, probably one of the most difficult disinfections which the quarantine officer was called upon to perform. The best method was considered to be, first to mechanically cleanse the vessel, then to wash same down with a strong solution of caustic soda, after which to wash everything down with a 1-to-500 solution of bichloride of mercury; after that, thoroughly to repaint the vessel. If this was done carefully, it could be reasonably expected that the anthrax bacilli and their spores had been killed.

The next subject under discussion was a short address delivered by Captain and Assistant Surgeon Ford, of the United States Army, upon the results of serum treatment in malaria. He stated that he had prepared a serum by taking infected human blood and injecting same into white rabbits and afterwards withdrawing from them the serum, injecting this into the human subjects for the cure of malaria. He stated that in a large percentage of cases this method of treatment had been successful, but that failure had resulted in several cases. He stated that he had undertaken this form of treatment, not so much on account of the fact that quinine was regarded as unsatisfactory in the treatment of malaria, but for the purpose of ascertaining whether the serum prepared with animal organisms like those of malaria could be depended upon to produce antitoxic substances, and from his experience he was inclined to believe that this had been fully demonstrated in his cases.

Cases of diphtheria and measles still continue to occur in the city of Manila. This is the first time that so many cases have come under observation since American occupation. The cases of measles are confined to American children almost exclusively. It is thought possible that this is due to the infection being contracted at the public school which they attend. Diphtheria also continues to occur, mostly among American children, although a few Filipinos have been infected. One death in an American has occurred up to the present time. Cases occur on an average of three or four per week. In the past it was possible in most instances to trace them direct to importations, but this time it has not been possible to do so.

Cholera still continues in Manila and nearby towns, but so far there has been no spread by maritime routes. During the early part of November the disease was reported as being present at Camp Overton, which is situated near Iligan, Mindanao, but up to the present time it is not known whether the same has been definitely diagnosed as cholera or not. Only a few cases have occurred. In the city of Manila there has been about one case per day during the past few weeks. There has been some spread along points situated on the railroad which leads out of the city of Manila. Total cases in Manila from November 1 to November 23, 26; deaths, 23.

Progress of Medical Science.

Boston Medical and Surgical Journal, January 9, 1908.

Chronic Dyspepsia.—J. B. Deaver declares that this term denotes a symptom-complex which is usually expressive of distinct organic disease within the abdomen. The cause of chronic dyspepsia is chronic disease in the gastro-enteric canal of associated glands and the author devotes his consideration of the subject to treating of the diseases of the appendix, stomach, and duodenum, and of the biliary passages as producing chronic dyspepsia. He notes that when the appendix is the seat of noninflammatory irritation it is a common occurrence for the patient to be treated for dyspepsia and constipation with no permanent result. Of the intrinsic diseases of the stomach the most common is ulcer or the same lesion in the duodenum, and after that, in the author's experience, cancer. Such cases go on with the usual antidyspepsia treatment until a sudden hemorrhage wakes the physician up to the real nature of the case. The author believes that it is not unreasonable to state that the majority of cases of gastric cancer arise in the bed of an old ulcer. If a cancer of chronic dyspepsia has been treated for a considerable time medically and has not improved he should undergo a thorough abdominal examination. The stools should be examined chemically and microscopically, and if the diagnosis cannot be definitely made and the symptoms persist, the question of opening the abdomen should always come up for serious consideration.

New York Medical Journal, January 11, 1908.

Causes of Appendicitis.—A. W. Armstrong enumerates the predisposing causes of appendicular inflammation, as follows: (1) The degenerate condition of the organ itself. (2) The structure of the appendicular walls and their blood and nerve supply. (3) Its form and direction. (4) Normal drainage. (5) Diet and chronic constipation. (6) Mechanical obstruction and stricture of the lumen. (7) Constitutional diseases. (8) Disease of the pelvic organs. The list of exciting cases is shorter, including as it should: (1) Traumatism. (2) Intestinal parasites. (3) Enteritis. (4) Direct infection. The author elaborates each of these

headings and closes by saying that it must be said that the pressure of a pathogenic germ is the one thing constantly necessary to the production of this condition. Simple necrosis of an organ so functionally inactive and useless as the appendix would not be expected to give rise to serious symptoms, it must rather become infected. There is no special germ, however, that can be charged with the burden of having been introduced into the appendix for this special occasion—in fact, the germs involved in the process are normally present in the appendix in health, awaiting the time when some accident shall bring about a condition suitable for their work. The *Bacillus coli communis* and the ordinary pyogenic cocci are most commonly present, and whatever the assigned cause may be it must be remembered that appendicitis is an infective malady.

Cerebral Contusion.—C. S. White says that in cerebral contusion, there is a period of unconsciousness immediately supervening which may last from a few moments to as many weeks. The face is pale, cold, and often moist; the pupils usually dilated, reacting to light; the pulse full, compressible, between 70 and 90; the respirations free; the temperature subnormal, and the blood pressure below 110. There is no involuntary evacuation of feces or urine, and the patient lies quietly. A period of reaction soon occurs, the skin becomes warmer, the pulse firmer, the person may become restless; he can be aroused by a vigorous shaking and perhaps give monosyllabic answers to questions shouted in his ear. In a case in which the contusion is slight or mild, the mentality is impaired for a brief period, and in an hour or two he may give intelligent answers and in other respects appear responsible. Headache and nausea may be an accompaniment, with mild constitutional symptoms. Treatment calls for moderate stimulation, preferably with strychnine, rest, ice-cap to the head and heat to the body. Excited states should be controlled by the bromides. Purgatives are often sufficient in the very mild cases. Opium is generally contraindicated. In the profound cases where symptoms of pressure supervene it is best to trephine over the middle meningeal artery. The author's general conclusions are as follows: (1) Cerebral contusions, when fatal, are due to laceration or hemorrhage. (2) Prolonged coma is a reliable indication of increased pressure. (3) A conscious period followed by coma indicates hemorrhage. (4) High blood pressure is an early and reliable symptom of pressure. (5) Trephining is indicated in plus intracranial pressure from hemorrhage or edema. (6) Venesection is of doubtful value. Two personal cases are reported.

Acute Pulmonary Edema as a Complication of Epileptic Seizures.—W. T. Shanahan states that in all grand and in many petit mal seizures there is a more or less marked increase in the secretion of mucus along the respiratory passages with the subsequent frothing at the mouth which is commonly seen in such patients. In some cases there may be no actual increase, but simply an accumulation in the mouth of the normal amount which is then forced from between the lips during the accentuated respiratory air currents which accompany the stertorous type of breathing. In a few cases this great outpouring of mucus becomes so marked that the patient is in actual danger of being drowned in his own secretions, this acute process producing a marked pulmonary edema. Eight personal cases are reported. In such cases an enfeebled action of the left ventricle renders it unable to expel in a unit of time the same quantity of blood as does the right ventricle, the resistance remaining the same. As a consequence of this there is some large excess of blood in the pulmonary vessels. The edema is usually associated with venous hyperemia. The asphyxia accompanying the seizure is caused by the local stagnation of the blood stream and in turn causes an increase in the permeability of the endothelial walls of the lung capillaries. As to treatment, the author notes that the most important procedure has been found to be a change of posture so as to aid in draining the respiratory passages of the great excess of mucus. If necessary, turn the patient over the side of the bed, removing all mucus from the mouth, nares, and pharynx. Open the mouth with a gag or with the fingers protected by a towel. In addition, much benefit has been obtained by dry cupping and the use of atropine and strychnine hypodermatically Venesection is of value in full blooded patients. Adrenalin was used without apparent result.

The Voice as an Index to Diseases of the Throat, Nose, and Ear.—G. Hudson-Makuen calls attention to the voice as an index of man's mental and moral as well as physical state. With reference to the latter he discusses the hoarse, throaty, tremulous, muffled, whispered falsetto and nasal voice. He notes that a common cause for the characteristic hoarseness of incipient tuberculosis is the thickening of one or both ventricular bands which interferes with the normal approximation and vibration of the cords. Hoarseness is frequently symptomatic of intralaryngeal tumors. The tremulous or broken voice is characteristic of age, but is often noted in those who are debilitated by overwork and especially by extraordinary vocal effort. The whispered voice is well illustrated in hysterical aphonia. The voice of the deaf is of high pitch, and monotonous and throaty. It is unmodulated. The muffled voice is one that is more or less devoid of head resonance. It is the voice of those having faucial and pharyngeal tonsils, hypertrophied turbinals, nasal polypi, or other nasal and pharyngeal growths. The nasopharyngeal resonators are dampened, so to speak, and the voice is muffled. The falsetto voice is generally indicative of no special throat, nose, or ear lesion, and it is due entirely to an erroneous conception of the true tones and a consequent misplacement of the tones. There is in it no laryngeal or chest resonance, but the larynx is markedly elevated and the vibrations are focused high up in the head. The nasal voice is due in the majority of instances to inadequacy of the velum palati, which allows too great a proportion of the vibrating breath to pass up through the nasopharynx, thus giving a preponderance to the nasal resonance.

The Lancet, January 4, 1908.

"Diphtheria of the Skin" of Three Years' Duration Treated by Antitoxin.—The history of an unusual case is given by A. R. Slater, whose patient was a girl of thirteen years. Three years before she had had an inflammation of the eyes and shortly afterward a white patch was noticed on each labium. Soon blisters began to develop around the vulva and spread on to the abdomen. The child was then taken to a general hospital and was admitted, the vesicles having spread so rapidly that she was practically covered by them about the body and neck, and there were a few on the face and head. She remained in the hospital about five months and during that time made little or no progress, the only change being that the abdomen cleared and the vesicles were confined to the parts round the vulva, the chest, the neck, and the head (including all the face). Since then she had been treated for syphilis, a section taken of one of the vesicles showing some appearance of syphilis, but this plan of treatment was of no apparent benefit. When the child came under the author's observation, she presented masses of vesicles round the left side of the mouth extending to the cheek, but not into the mouth; others on both eyebrows, the right being worse than the left. The external meatus of both ears was filled with thick semipurulent discharge, the lobes of the ears and behind the ears being covered with discharging vesicles. Upon the head were large masses of vesicles and some dried scabs where former ones had been. The neck and shoulders had large quantities of vesicles on them extending down to the nipples on either side and as far as the middle of the scapulæ on either side at the back. In the areas affected the space between the vesicles was dark red, but in other areas which had been affected and where the vesicles had disappeared the skin was only slightly erythematous or even normal, no scarring being left behind. The region of the vulva was erythematous and studded with vesicles, but this condition did not go back further than the vulva itself; the whole affected area thereabouts extended to three or four inches down the inner part of the thighs and about four inches up the abdominal wall. All the areas were discharging freely, a thin, clear fluid dripping from the chin at the rate of a drop per minute. Examination of the fluid showed the presence of a bacillus corresponding in reaction and inoculation experiments to that of diphtheria and she was immediately given injections of antitoxin under which improvement was steady and finally complete. Staphylococci were also found in the exudate. The disease apparently had commenced in the eyes, then spread to the vulva, and thence into the superficial lymphatic circulation producing a condition resembling herpes. The lesions were confined to the superficial skin layers, as no scarring was left.

An Unusual Pathological Condition of Meckel's Diverticulum.—C. H. Turner's patient was a man of 23 years who was taken with violent abdominal pains and vomiting. On admission to hospital, a diagnosis was made of acute appendicitis with fairly extensive localized peritonitis. On opening the peritoneum about six ounces of turbid peritoneal fluid escaped, and distended and somewhat congested coils of small intestine presented. The cecum could not be felt in the iliac fossa nor could any large intestine be pulled out. The incision was extended a couple of inches and the whole hand was introduced. A portion of the large intestine could then be felt quite collapsed and lying high up. This was pulled down easily and traced first in one direction where it was found to be continuous

with the transverse colon; traced in the other direction it was found to take a turn upwards and forwards towards the umbilicus, and here a slight adhesion gave way and the cecum was brought out of the wound and examined; it was also collapsed and the appendix was found to be healthy. The ileum was then followed up and the first foot was collapsed and found to be firmly adherent at this point to the anterior abdominal wall, just at the level of, and to the right of, the umbilicus. The first incision was covered up with sterilized gauze and a second incision three inches long was made through the fibers of the right rectus muscle. On incising the posterior layer of the sheath of the rectus what was apparently an abscess cavity containing four ounces of very offensive pus was opened. This was swabbed up and washed out with 1 in 40 carbolic lotion and then explored with the finger; the walls were quite smooth and felt as though formed by mucous membrane. The peritoneal cavity was opened next and carefully packed off. The abscess cavity described above was then found to be the inner surface of the fundus of a dilated and gangrenous Meckel's diverticulum, which was adherent to the anterior abdominal wall. It was then carefully separated and the coil of bowel from which it arose was drawn out of the wound. The diverticulum arose from the ileum, about twelve inches from the ileocecal valve; its proximal portion was stenosed and its distal portion or fundus was gangrenous and dilated (as far as could be judged, for it had contained four ounces of pus) to the size of a Tangerine orange. Recovery was complete in fourteen days.

Delirium Tremens.—L. N. Boston gives a tabulated analysis of 156 cases. The condition is most common between the ages of 30 and 50, while the death rate is practically the same for the second, third, and fourth decades. The author's statistics show that the same patient may suffer numerous attacks and that contrary to the general belief the condition does not result fatally in the second or third attacks. Most of the cases occurred during August (Philadelphia). Twenty-two of the cases displayed more than one preexisting or complicating condition of which ten displayed kidney and lung involvement; seven heart and lung; two kidney and heart; and three heart and stomach. Thirty-eight of the 140 cases were uncomplicated and all of these were followed by recovery. Most striking in connection with the table enumerating accompanying lesions is the fact that all of the fifteen cases showing renal complications terminated fatally. Again, great importance is to be attached to the prognostic significance of pre-existing cardiac disease which gave a mortality rate of 84.6 per cent.; and acute cardiac complications are of but little less importance as regards the seriousness of the condition in question. Those cases developing acute pulmonary conditions (bronchitis and bronchopneumonia) gave a death-rate of but 66 per cent.

British Medical Journal, January 4, 1908.

A Note on Nephropexy.—F. Eve describes the operation which he has been in the habit of doing for anchoring the kidney. The main features are summarized in the following propositions: (1) Owing to the friability of the renal tissue the capsule only should be used for its fixation. (2) A decorticated surface of the kidney should be brought into immediate relationship with the quadratus lumborum and psoas on which it normally lies without the intervention of any connective tissue. (3) No sutures should be affixed to the capsule of the kidney in its upper third, as when passed through the parietes they would as a rule fix the kidney in a position below that which is normal. Technical details are given in the original paper.

Excessive Patellar Reflex of Functional Nervous Origin, and Especially the "Trepidation" or "Spinal Epilepsy" Form.—According to F. P. Weber, the excess in the patellar reflex in the class of cases under consideration is due to a peculiar functional condition of the cerebral cortex, which when present in greater degree gives rise to the "trepidation" form of patellar reflex, and to the so-called "spinal trepidation," and to "functional ankle clonus"; that this functional condition of the cerebral cortex may be excited or modified by temporary emotional factors, and that a similar state may be induced by toxemias, such as uremia; that the signs (exaggerated knee jerks, etc.) of the functional cerebral condition in question may be imitated by organic nervous disease (cerebral hemorrhage, sclerosis in the lateral columns of the spinal cord, disseminated sclerosis, etc.), but that it is just possible that in some rare cases of organic nervous disease (for instance, some cases of early disseminated sclerosis) the organic changes may give rise to the phenomena of increased tendon reflexes, etc., merely by inducing the above-mentioned (hypothetical) functional cerebral change. The author gives a further illustration of his meaning by an allusion to the analagous question of the nature of functional nervous vomiting where, he maintains, we probably have to deal with a peculiar functional change in the brain (cortex), analogous to the cerebral condition that produces the exaggerated tendon reflexes and "trepidation" of functional nervous origin, and which, like it, may be excited or modified by emotional factors, and is analogous to certain states induced by toxemias—such as uremia. The symptoms produced by these abnormal functional states may equal or even exceed those produced by organic disease.

Typhoid Carriers.—A. Ledingham and J. C. C. Ledingham refer to those cases of typhoid in which after recovery the patients still void typhoid bacilli in the stools and are consequently a menace to those about them. Reference is made to various reports of this class of cases. Lunatic asylums appear to yield a considerable number and the authors record their personal experience in an asylum under their control. Cases of typhoid appeared from time to time without any apparent cause. Fifty-seven samples of feces from female patients were examined. One patient, G., was found to be passing typhoid bacilli in enormous numbers in the feces. In fact, the plates contained typhoid colonies to the almost complete exclusion of *B. coli* and other lactose fermenters. This patient, G., has been in the asylum since 1896. She is thirty-five years of age, suffers from dementia, and there is no record of her having had typhoid fever. Her personal habits are exceedingly filthy, and she has never been employed in the laundry or kitchen. Her serum agglutinated the *Bacillus typhosus* up to 1 in 200. With the isolation of this case, the fever was, it was hoped, checked, but another case came up and fresh examinations of the feces were made. Another typhoid carrier was thus brought to light and later still another. It seems probable that in these cases the bacilli vegetate in the gall-bladder from which they are intermittently ejected into the bowel. Such "carrier" patients should of course be kept under constant bacteriological supervision. In two instances Dehler performed cholecystostomy and drainage of the gall-bladder though in neither case was there any direct evidence of disease of this viscus.

The Contents of Irreducible Inguinal Herniæ in Female Subjects and True Hermaphroditism.—E. M. Corner states that there is a condition of inguinal hernia found in females which deserves much more attention than has hitherto been given to it. It is concerned with the irreducibility of the hernia, and differs in a most marked manner when found in adults from that when found in children. This condition is the presence of some of the female internal genitalia in the hernial sac. Statistics collected by the author demonstrate the fact that an irreducible hernia in a female infant is almost sure to contain some of the internal genitalia. He lays down the following rules: (1) When *irreducible*, the hernia of a female child will be felt to contain a small rounded body, about the size of a small pea, which is freely movable upon its pedicle. It is the ovary. (2) When *strangulated*, there is an irreducible nontranslucent mass over the external abdominal ring through which it protrudes. If it does not contain bowel, as was only found in fifteen per cent. of the irreducible female herniæ of infants, there need be no sickness and the bowels will act. The lump gets larger and larger, but, strange to say, may cause the infant very little inconvenience. This seems to be accounted for by the strangulation of the tube and ovary causing the distention of the ovary and tube with blood and serum, producing in time a kind of an infiltration anesthesia. Otherwise it is hard to understand the apparent painlessness of the hernia. When the hernia is simply irreducible the tube and ovary can be easily felt. When the hernia is strangulated and has no impulse on crying, the diagnosis is easily made by the nontranslucence of the swelling and the association of it with no more symptoms than, perhaps, some slight irregularity of the bowels and the digestion. Corner notes another imperfectly known and most interesting feature of the generative glands found in the orignal hernial sacs of female children. If they are removed and examined with the microscope in some cases they will be shown to be immature testicles and not ovaries. When this is so, the case is truly hermaphrodite, male generative glands and female generative organs. On this account it has been advised that those glands be removed so as to avoid the child growing up to be an imperfect man. This is extremely doubtful advice, because an emasculated being is not female, but of a neuter sex, and has been deprived of certain perfected secondary characteristics, such as bodily and mental energy.

Berliner klinische Wochenschrift, December 30, 1907.

Suboccipital Disease.—Grünwald says that this term includes not only tuberculosis of the bones at the base of the skull, but also inflammatory processes of infectious nature involving these joints, the neighboring tissues, and fascial planes. Such processes may originate from affections of the ear as the result of trauma to the base of the skull, disease of the accessory cavities of the nose, the teeth, and finally syphilis. The inflammatory process may give rise to a considerable variety of symptoms, according to its course and the structures it invades, but certain typical signs are always present. Prominent among these are the more or less pronounced rigidity of the neck and the early onset of pain involving the distribution of the trigeminal or occipital nerves. In the later stages the presence of infiltration at the back of the neck indicates the site of the morbid process, while rupture into the retropharyngeal space is less significant. The original focus can often be determined only through a careful chronological and topical study of the symptoms, and the primary lesion frequently remains latent for a considerable length of time. Evidence of rupture, such as sudden cessation of pain, or diminution in the fever, and the rigidity, is of great importance, as it indicates the invasion of wider districts by a previously localized process and points out the last moment at which immediate intervention may still prevent grave, if not fatal, consequences. Careful scrutiny of the temperature curve is particularly useful in keeping track of the course of the infection and in recognizing this critical period at which extension begins. Before actual suppuration occurs it is advisable to adopt palliative measures, such as immobilization of the head, with or without traction. The author describes in detail five such cases having various primary foci of infection.

Münchener medizinische Wochenschrift, December 31, 1907.

Late Lesions of the Ulnar Nerve.—Brassert says that it is not generally recognized that affections of the ulnar nerve may sometimes be the result of injuries or other changes about the elbow joint occurring years previously and giving rise to the formation of callus or cicatricial growths. The immediate cause of such a lesion may be sudden strain or overexertion. While several such cases have been reported their number is comparatively small and the author contributes another. The patient was a machinist forty-eight years of age who presented himself complaining of pain in the right arm with numbness of the fourth and fifth fingers which had lasted over a year, and for five or six weeks had been accompanied by weakness of the fingers mentioned which was a hindrance in his work. An analysis of the symptoms presented indicated that a paresis of the ulnar nerve existed and no etiological moment for this could be discovered except a scarlatinal infection thirty-three years previously which had been accompanied by suppurative arthritis in both elbows and in one knee. Roentgen ray examination of the right elbow showed that there was thickening and bony hyperplasia about the joint involving the lower end of the humerus and the upper extremities of the radius and ulna which were considerably deformed. The author assumes that as the result of this periarticular change the nerve trunk was pressed upon or changed in course so that decades after the primary arthritis the nerve lesion manifested itself. The occupation of the patient might perhaps serve as contributing cause. No other etiological factors could be discovered.

Deutsche medizinische Wochenschrift, December 26, 1907, *and January* 2, 1908.

The Diagnosis of Diaphragmatic Pleurisy.—Sehrwald says that while in cases of pleurisy in which a considerable area is involved the diaphragmatic pleura is probably often affected also, it is difficult in most cases to make this diagnosis. Among the symptoms indicating inflammation of the diaphragmatic pleura are the following: Diminution or absence of the movement of the diaphragm, giving rise to very rapid, syncopated, costal respiration, with excessive dyspnea that may even reach the grade of orthopnea. On the diseased side the diaphragm is higher than normal. Constipation and jaundice may also be present. There is severe pain at the insertion of the diaphragm, which is brought on by motion such as that of respiration, coughing, belching, hiccough, etc. There is tenderness in the epigastrium and along the twelfth rib, sometimes between the insertions of the sternocleidomastoid muscles, owing to tenderness of the phrenic nerve. Tenderness also may exist at the point of intersection of the line continuing the external border of the sternum and the horizontal prolongation of the tenth rib, and at another point in the eleventh intercostal space close beside the vertebral column. On deglutition there may be pain as the food passes through the esophageal opening in the diaphragm, and in a case of the author's severe paroxysms of coughing were induced in the same way. Gastric irritation may lead to pain, hiccough, and vomiting. The respiratory abdominal reflex may be present, consisting of a lightning-like contraction in the upper portion of the rectus muscle on the side involved appearing at the end of deep inspiration. Friction sounds over the diaphragm may be present and peritonitis may result from secondary involvement of this membrane.

Esophagoscopy in Carcinoma of the Esophagus.—Elsner, in discussing the value of esophagoscopy as a diagnostic measure, says that while there is no doubt of its utility in cases of impacted foreign bodies, its position in regard to malignant disease of the esophagus is less clear. From this standpoint cancer of the esophagus may be divided into two types, that involving the tube itself and that of the cardia. When the disease is in the former situation its nature can nearly always be determined without great difficulty by means of the older diagnostic measures, but the picture of cancer of the cardia is less clean cut and more likely to be confounded with that of other conditions. In cases in which the disease is supposed to be in this situation the esophagoscope may prove of great service in clearing up the diagnosis. On the other hand, it must be admitted that at present the early diagnosis of esophageal carcinoma has not the same importance as that of the stomach, for example, since as yet the organ is inaccessible to operative procedures.

The Treatment of Nevi and Teleangiectases.—Ogata recommends the following preparation as a local application for the removal of nevi and teleangiectases. Rice grains are washed and placed in a glass dish; ten per cent. potassium hydrate solution is poured over them and they are allowed to stand six to eight hours after they have become thoroughly softened. The starch of the rice grains swells up and gradually becomes transparent. When the grain has become entirely clear the alkali solution is poured off and the sediment is washed with water. The mass so obtained is triturated in a porcelain mortar and forms a colorless, sticky mass, strongly alkaline in reaction, and consisting of a combination of starch with potassium hydrate. Through the union with the starch the caustic properties of the alkali are considerably reduced and the tissues are not invaded too deeply. The preparation loses its strength in about six hours and therefore must be freshly prepared. It is applied by means of a pointed glass rod after the skin has been cleaned with tincture of soap and dried off. Several applications can be made at a single session, the area being washed with sterile salt solution each time after the caustic applied has dried. In children it is advisable to apply five per cent. cocaine solution before the caustic. In most cases three to five applications are sufficient, the area treated becoming black and being cast off in from seven to ten days. The scars are at first red, but later whiten and become entirely invisible. It is important not to treat too large an area at a time, otherwise disfiguring scars due to suppuration may result. Lesions of considerable size require a treatment of months or even a year.

The Surgical Treatment of Hyperacidity.—Balas reports three cases of extreme hyperacidity which were successfully treated by the operation of gastroenterostomy. In two of the cases there was no stenosis, while in the third the stomach was of pronounced hour glass type and there was a tight cicatricial stenosis of the pylorus, the condition evidently being secondary to ulcer. Examination of the gastric contents after the patients had recovered from the operation showed the presence of bile and pancreatic juice, these secretions having entered the organ through the intestinal opening. The author believes that Katzenstein's theory in regard to the beneficial effects of gastroenterostomy in cases of hyperacidity is the correct one. This is that the entrance into the stomach of bile and pancreatic secretion in these cases is beneficial through the chemical neutralization of the gastric juice and also through a reflex inhibition of gastric secretion which is thus caused.

Treatment of Septic Wounds.—For wounds that are septic or have an offensive discharge, Joseph Mullen advises dropping twenty drops of 40 per cent. solution of formaldehyde on the dressing three times a day. The effect on the wound is excellent, the dressing does not require such frequent renewal, and the odor of the discharges is eliminated.—*Medicol Recorder.*

Book Reviews.

The Teachings of Thomas Henry Huxley. By Irving Wilson Voorhees, M.S. (Princeton), M.D. (Columbia). New York: Broadway Publishing Company, 1907.

In this appreciation of Huxley's life and work the author first pays a tribute to the man himself and then rehearses briefly the great scientist's views in regard to the most important of the many fields of learning he explored These are discussed under the headings of his teachings concerning biology, theology, education, morals, work, individual rights, and psychology. The little book is written with understanding and due realization of Huxley's part in molding the opinions now held on many different subjects and should prove a potent incentive to further study of his writings.

Materia Medica, and Pharmacy. By Reynold Webb Wilcox, M.A., M.D., LL.D., Professor of Medicine at the New York Post-Graduate Medical School and Hospital, etc. Philadelphia: P. Blakiston's Son & Co., 1907.

Wilcox's work on Materia Medica and Therapeutics is a successor to W. Hale White's book on the same subject. The work was for a time known as White and Wilcox's, but as the last editions have been entirely rewritten by Dr. Wilcox, his name alone now appears on the title page. In the present edition many additions have been made, rendering the book so bulky that it was divided into two volumes. Of these the present volume forms Part I., being devoted to Materia Medica and Pharmacy, while the second volume deals with Therapeutics. The various drugs and preparations are described in detail, and are grouped according to chemical and physiological relationship. Chapters on pharmaceutical processes and on prescription writing are also presented. The book is a very practical one and will appeal especially to medical students and teachers at medical schools, although it is excellent also for quick reference for the busy doctor. The first volume alone cannot, however, be used as a guide to therapeutics, for it contains only the briefest references to the action and use of drugs.

Pharmacology and Therapeutics. By Reynold Webb Wilcox, M.A., M.D., LL.D., Professor of Medicine at the New York Post-Graduate Medical School and Hospital, etc. Philadelphia: P. Blakiston's Son & Co., 1907.

The second volume deals, as its title states, with the applications of Materia Medica in the art of treating disease, and is an indispensable companion to the first volume. The second part can be used alone also, by the practitioner who is content to have a good work on therapeutics without the details which concern more especially the pharmacist. The volume offers a very complete description of the action and uses of drugs, according to the highest standard authority. It deals chiefly with the drugs of the U. S. P. (the latest revision being followed), but also contains references to the most commonly used unofficial remedies. A preliminary section is devoted to general matters, the modes of administering drugs, dosage, and theoretical considerations. The drugs are then taken up in groups according to their action—an excellent and most reasonable classification. Chapters on organic extracts, serums, and antitoxins are appended, while an index of diseases and symptoms helps in the search for any drug for the particular clinical case which one is treating

Blood-Stains: Their Detection and the Determination of Their Source. A Manual for the Medical and Legal Professions. By Major W. D. Sutherland, of His Majesty's Indian Medical Service. New York: William Wood and Company, 1907.

This manual gives the methods for determining the origin and character of blood-stains; the solubility, chemical tests, spectroscopical and microscopical examination; the serological tests by agglutinins, hemolysins, precipitins; and other authoritative information which will lead to the identification of blood-stains whether of man or other mammal and their approximate age. A number of cases of crime are referred to, giving the history and means employed to determine the medicolegal status of the case. Chemical tests are numerous and complete, while the serological tests, as detailed in Chapters VI. to X., are not only valuable, but afford highly interesting reading.

The Pathology of Fermentation. By Alonzo Englebert Taylor. Berkeley: University of California, Publishers, 1907.

We have here a series of lectures delivered at the University of California in 1904 and 1905. The delay in their appearance in book form is due to the San Francisco fire, April 18, 1906, when some portion of the manuscript was lost. Fermentation is here treated from its numerous points of view: catalysis or chemical decomposition produced by the presence of a substance which does not itself enter into the reaction. Fermentation of the carbohydrates, of protein, of fat; the nature of ferments and the reactions of fermentations; the specificity of ferments and the rôle of fermentation in metabolism. It would be impossible to enter into a descriptive review of these highly important and interesting processes. A specific reference, however, is called for to the chapter on the relation of fermentation to metabolism. This particular portion of the book is of great value and should be highly appreciated by the physician. It is doubtful, however, if the average medical man is sufficiently versed in organic chemistry to follow these studies. To the physiological chemist, or one who has a working knowledge of laboratory experiments, this as well as the whole book will be especially valuable.

Die Zuckerkrankheit und Ihre Behandlung. Von Professor Dr. Carl von Noorden, Vorstand der I Medizinischen. Universitätsklinick in Wien. Vierte Auflage. Berlin: August Hirschwald, 1907.

This familiar work of one of the greatest authorities in the world on diabetes appears now in its fourth edition, the first to be dated at Vienna instead of Frankfort-on-the-Main. The present edition has been not only scrupulously revised but in a large measure rewritten, especially as regards the portions dealing with the acetone bodies, and with the treatment of the disease. The book is intended for practitioners and therefore the theoretical parts have been much shortened. The reader is referred for these to the elaborate critical discussion of the entire scientific material on the pathology and chemistry of diabetes in the author's larger work, "Handbuch der Pathologie des Stoffwechsels," Vol. II., which has appeared this year in an English translation. The clinical portions of the book in this edition contain statistics and data concerning 2,500 cases of diabetes treated by the author since his establishment in Frankfort in 1804. The book is of the greatest practical value, especially on the subject of diet and treatment to all those who are interested in the still mysterious disease, diabetes.

Vorlesungen über Magen und Darmkrankheiten. Von Hofrat Dr. Friedrich Krämer. 3 Heft: Die Einwirkung der Genussmittel auf der menschlichen Organismus, Speciell auf die Verdauungs-Organe. I Tabak, Kaffee und Thee und Verdauung. II. Alkohol und Verdauung. Munich: J. F. Lehmann, 1907.

Dr. Krämer's lectures on the influence of coffee, tea, and alcohol upon digestion constitute a valuable contribution to the study of this important question. The author presents a great amount of clinical, statistical, and experimental evidence showing the bad effects of the abuse of these stimulants. He dwells especially on the anomalous fact that temperance movements have devoted themselves particularly to alcohol, ignoring the great evils of coffee, tea, and tobacco in excess. Tobacco, coffee, and tea, in large quantities, act most seriously upon digestion. Excessive smoking is, in his opinion, one of the chief causes of arteriosclerosis. The use of coffee and tea as substitutes for alcohol is wrong, for a moderate use of alcohol is not as injurious as that of large amounts of coffee and tea. Those who flatter themselves that they are temperate because they do not "touch a drop" of alcohol, but smoke all day long, are laboring under a vain delusion. The author recognizes, however, that a moderate amount of alcohol, with or before meals, acts as a digestive stimulant and is not injurious.

International Clinics. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles Edited by W. T. Longcope, M.D., Philadelphia, U. S. A. Vol. III., 17th Series, 1907. Philadelphia: J. B. Lippincott & Co., 1907.

This new volume of International Clinics contains, as usual, much of interest to all classes of physicians and much of special worth to those who study single lines of medical science. It is impossible to enumerate all the articles contained in the volume in detail, and it is scarcely fair in view of the general excellence of all, to select a few for comment. Without reflecting upon the quality of the rest of the papers, we might mention some that will particularly appeal to the practitioner. The article of Dr. Edsall of Philadelphia on diabetes will appeal to those who wish a summary of some of the results of modern researches in this field. Raymond Wallace of Tennessee contributes a short but very instructive paper on the modern views of renal disease, and F. K. Green and Q. W. Hunter one on anomalies of menstruation. One of the most practical papers in the book is that by L. Brocq of Paris on the removal of superfluous hair

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held December 6, 1907.

DR. JOHN F. ERDMANN IN THE CHAIR.

Perforated Duodenal Ulcer.—Dr. CHAS H. PECK presented a man, 45 years old, who worked in a garage. This was a case that he wished to add to the series of cases reported at the last meeting. There was no previous history of gastric trouble except pain in the abdomen, which laid him up for two days two years ago. On the morning of his admission to the hospital, November 1, 1907, he lifted a heavy tank of gasoline above his head in the garage, when he was seized with severe abdominal pain, faintness, and nausea, and was compelled to discontinue his work. The pain continued and he was taken home and seen by a physician who gave him morphine. Throughout the day the pain continued. During the evening the tenderness and rigidity made a serious abdominal trouble seem likely and he then was sent to the hospital, about twelve or thirteen hours after the onset of the pain. His temperature was 101°, and pulse 90. The polymorphonuclears were 93 per cent. The tenderness and the rigidity and other symptoms made them think that possibly the patient was suffering from an attack of appendicitis. The appendix was removed but proved to be practically normal. A second incision was made and a small perforation in the duodenum, close to the pylorus, was found. This was easily closed and the man made a prompt and uneventful recovery. An interesting feature in this case was that the man was burned about the face by gas some three weeks previously, but it was such a slight burn that it probably had but little if any influence on the development of the duodenal ulcer. The patient was out of the hospital in sixteen days.

Dr. SAMUEL LLOYD congratulated Dr. Peck upon the results obtained. He remembered a case that was reported some time ago; a man was found with a perforation, was operated upon, but died of starvation two weeks after. Sometimes they made a mistake, he believed, in not taking more risks in these cases. He questioned if they could not get prompt union if the patient could not stand a plastic operation, closing the pyloric end of the stomach and establishing a fistula directly into the duodenum, feeding through it; this, he thought, might be an advantageous method. By establishing such a fistula and feeding through it, one might be successful in tiding the patient over until a more radical operation could be performed.

Dr. HENRY W. BERG said he had had the misfortune to see a number of these cases a while after perforation; in two cases one week or ten days had elapsed and a periduodenal abscess had formed. Dr. Peck's patient was fortunate; a few hours after perforation he was able to cut down upon the parts and put in a purse-string suture. Where one was fortunate enough to see these cases early after perforation he did not think there was much doubt as to the safety of the suture line providing there was not too much infiltration. When these cases were seen several days after the perforation, when the site of the perforation was surrounded by a deposit of fibrin and pus, the suture line then must be made in infected tissues; again, where the ulcer itself was surrounded by thickening and an infiltration area, he thought the best results were obtained by an immediate gastroduodenostomy and pyloric occlusion.

Dr. JOHN F. ERDMANN asked Dr. Peck if there were any preliminary digestive symptoms in the case reported. Personally he had had eleven or thirteen cases and in the majority of them there were no preliminary digestive symptoms whatever.

Dr. Peck said this was the eighth case he had had of perforated gastric or duodenal ulcer. The man presented gave no history of preceding digestive symptoms, but the other cases all gave a history of indigestion and at least two or three gave symptoms quite suggestive of ulcer. The case presented offered no technical difficulties and therefore was of no great credit to him. In some cases of perforation, the sewing was easy. But he did not get any leakage. By passing the suture deeply into the tissues and tying them just enough to get closure without cutting through, and burying all, one would get a satisfactory closure. He said he had had no experience with perforating duodenal ulcer except in one case, and he was therefore unable to draw any conclusions.

Dr. SAMUEL LLOYD said he would like to ask if any present had had any experience with gall-duct disturbances in these cases. He recalled one case with a preliminary jaundice and apparently the history pointed to difficulty along the gall-ducts, an obstruction of the gall-ducts.

Dr. Berg said, in answer to Dr. Lloyd, that he would look it up.

Dr. Peck said that no gall-duct disturbances had occurred in any of his cases.

Dr. ALEXANDER LYLE said that recently he had had a patient with jaundice and other symptoms which pointed to gall-bladder disturbances. She was operated upon for empyema of the gall-bladder, and he also found a perforation of the duodenum. The patient had gone on for one week or ten days after perforation and there was a large amount of induration present. The advisability of letting the mass alone at that time came up for consideration. The general abdominal cavity was walled off. Ten days later he went in with an aspirator and repacked; several repackings were done until the induration had disappeared and she was now well.

Gunshot Wound of the Abdomen, with Perforation of the Small Intestine, Bladder and Rectum; Laparotomy; Perineal Urethrotomy; Recovery.—Dr. HENRY ROTH presented a man, 46 years old, who was admitted to Lebanon Hospital October 2, 1907. About thirty minutes before admission he was shot at close range with a .38 caliber revolver, the bullet striking the anterior abdominal wall. He was able to walk across the street. The pain was insignificant. The temperature was subnormal and the pulse 80 and of good quality. He showed no evidences of anemia or shock. A perforation was found about one inch to the right and two and a half inches above the pubes. There was no wound of exit. A median incision was made between the umbilicus and pubes. The first loop of small intestines, which escaped after the peritoneum was incised, presented two perforations; they were about three feet from the ileocecal valve. About ten or more inches from the cecum two perforations were found in the ileum and two in the mesentery. The four perforations in the small intestines were closed with purse-string sutures, reinforced by Lembert sutures of silk, which were also used in closing the perforations in the mesentery. A perforation in the upper wall of the bladder was closed with Lembert sutures of silk. Another perforation was found in the posterior wall of the bladder and one in the anterior wall of the rectum. Both of these perforations were in the lower portion of the rectovesical pouch, and satisfactory suture was found to be impractical. A large cigarette drain was placed into the pouch with the projecting gauze in contact with the perforations of the bladder and rectum. The median incision was closed down to the drain. On account of strictures of the urethra and for the purpose of free drainage, a perineal urethrotomy was done and a No. 34 rubber catheter was left in the bladder. Two days

after the operation the bullet was removed from underneath the skin below the left-sacroiliac synchondrosis. It was presumed that the bullet took the following course through the viscera: After penetrating the peritoneum, it passed through a loop of bowel, causing two perforations; it then entered the upper wall of the bladder, passed through the viscus, causing a wound of exit. After its exit from the bladder, it caused two perforations in the small intestine, and two in the mesentery. It then went through the anterior wall of the rectum, traversed this organ, and out through the posterior wall of the rectum and pelvis, finally lodging underneath the skin. The bowels moved spontaneously on the fourth day after the operation, and on the ninth day after he passed urine voluntarily through the perineal incision. He was discharged from the hospital in November. His convalescence was practically uneventful except that, eleven days after the operation, he had an attack of anuria. Because of the hypodermoclysis a superficial necrosis resulted. The various wounds healed.

Dr. Alexis V. Moschcowitz said that one and a half years ago he had a case of gunshot wound of the abdomen and, with the exception of the injury to the bladder, the injuries otherwise resembled the case reported. A boy was shot with a gun, the point of entrance being two inches below the umbilicus and in the median line. At laparotomy eleven perforations were found, nine of them being in the small intestine, one in the rectum and one in the sigmoid flexure. There was no point of exit and he had never been able to locate the bullet. The presence of the bullet had given no symptoms whatever and the boy made a good recovery and was discharged twenty days after operation. Later symptoms of intestinal obstruction developed and there occurred many adhesions throughout the abdomen. After a serious siege the patient was again discharged cured.

Dr. Henry W. Berg asked how long after the last meal was the injury sustained.

Dr. Henry Roth replied that the man was shot at 10 A.M., and his last meal had been at 7 A.M.

Dr. Berg said that his reason for asking this question was that he thought the prognosis depended very much upon the length of time that elapsed between the last meal and receipt of the injury. It would seem that a wound received at the height of intestinal digestion gave a graver prognosis than if it was received a number of hours afterwards. At all events, he had a recent experience in which a gunshot wound was sustained within a half hour after the beginning of intestinal digestion, or two hours after the last meal was taken; a virulent peritonitis developed and the patient died.

Dr. John F. Erdmann said he had had an interesting case in his hospital service about three years ago. A woman was shot three and a half inches above the pubes in the central line. The bullet passed through the base of the bladder, through the vagina, through the rectum, and was picked up on the coccyx. A vaginorectal fistula was present, but the patient made a perfect recovery in a short time.

Dr. Henry Roth thought that the good result obtained was due to the fact that the patient was operated upon one and a half hours after he was shot. The greatest difficulty was in closing the perforation at the base of the bladder and anterior wall of the rectum.

Actinomycosis Six Years After Operation. — Dr. Henry W. Berg presented this case. The patient, a boy, came under observation six or seven years ago. A diagnosis of actinomycosis of the thoracic wall was made, this diagnosis being established by the presence of small but typical bodies and finding the fungus under the microscope. At that time he had an enormous discharging sinus in the anterior thoracic wall. On admission to the hospital he was poorly nourished. The fungus was obtained and the diagnosis established. After preliminary treatment an extensive operation was performed. Then almost the entire sternum was removed. The pleura was laid bare as well as the pericardium, and the mediastinum was exposed. Curettage was employed and the swabbing with iodine completed the operation. A secondary slight operation was necessary because of necrosed cartilage at the base of the sternum. Now, six years after the operation, the patient was entirely cured. The peculiar part of the operation was the almost complete regeneration of the sternum so as to cover the pericardium and pleura. He gained in strength and gave no symptoms of recurrence of the disease. He had been on iodide of potassium since leaving the hospital.

Head Trauma; Laceration of Cortical Face Center. — Dr. Clarence A. McWilliams presented a woman, 19 years old, who was brought by ambulance into the Presbyterian Hospital on August 24, 1906. She had fallen from a bridge, twenty feet high. She was unconscious for a few minutes and then became conscious, when she gave her name, etc. On admission she was unconscious and very restless. There was some bleeding from the nose, her pupils were small and equal and reacted to light. There was a moderate-sized hematoma over the left parietal region. No fracture of the vault was made out. Extending over the left mastoid region was a well marked ecchymosis. There was a fracture of the left clavicle. There were no paralyses, no loss of sensation, and the lower reflexes were normal. The patient was thought to have a fracture of the base. The temperature was 102°, pulse 80. Two days later, August 26, the patient was still stuporous and apparently unconscious of her surroundings. She had been so since admission. There was great restlessness and she could not be roused. The temperature was 101° and pulse 80. The left mastoid was very ecchymotic, as was also the right eyelid, but there was no subconjunctival hemorrhage. There were no focal symptoms. On August 27, the third day, the mental condition appeared to be a little clearer. Defecation and micturition were involuntary. The pulse was between 78 and 88, and temperature about 100°. There was thought to be a slight flattening of the right side of the face. On August 28, the fourth day, in the evening, she had a Jacksonian convulsion which began in the right corner of the mouth, then rapidly spread to the right eyelid, right hand, arm, and leg. The spasms were clonic and lasted about thirty minutes and were followed by complete relaxation. She acted in a wandering, unintelligible manner. The temperature was 100° and pulse 75. She had several of these convulsions during the night of the fourth day. On the morning of August 29, the fifth day, there was paralysis of the right side of the face with weakness of the right arm, though she was still able to move it. There were no definite sensory disturbances made out. The mental condition was stuporous, temperature 100°, pulse 76 and of good quality and regular. The leucocytes were 17,300 and polymorphonuclears were 75 per cent. The eye grounds were examined and appeared normal. There was no congestion of the retinal vessels. One ounce of perfectly clear fluid was obtained by lumbar puncture. During the afternoon of the fifth day, the convulsions came as often as every hour and it was decided to operate, and this was done during the evening of the fifth day after the fall, August 29, at 10:30 P.M. The fissure of Rolando on the left side was marked out and a curved horseshoe incision made. The trephine was applied about three and a half inches from the top of the fissure of Rolando. There was no epidural hemorrhage and no pulsation of the dura which bulged into the wound. On opening the dura, no hemorrhage was found and normal appearing brain bulged into the wound. A bipolar electrode was applied to the exposed brain area but there was no response in the right facial muscles. It was evident from this that they had

probably not uncovered the face center, that the trephine opening was too far posterior. The bone was rongeured away anteriorly for about two inches and on splitting the dura, an anteroposterior laceration of the cerebrum was exposed, three-quarters of an inch long and about half an inch deep. Stimulation of this lacerated area gave action, twitching of the face on the opposite side. In and about this laceration was some clotted blood. It was the opinion of the neurologists present that this laceration would account for all the symptoms presented. There was undoubtedly present a fracture of the base accompanied by more or less general edema of the brain. A slight laceration of the face center was caused by the original trauma. As the brain swelled from the increasing edema gradual increasing pressure was brought to bear on the laceration, whose edges yielded and rolled out from each other, thus enlarging it. The accompanying hemorrhage in and about the laceration by pressure helped to increase the progressive paralysis and the irritation thereby produced caused the convulsions. The dura was with difficulty sutured with catgut over the laceration because of the cerebral pressure. A small rubber drain was led through the dura to the laceration and brought out through the posterior angle of the skin wound, which was sutured with silk. The patient stood the operation well. She had numerous convulsions during the night following the operation. The last convulsion took place thirteen hours after the operation and she had had none since, it being now sixteen months since the injury. The second day her mental condition was much improved and she understood what she was asked to do. But she would not talk. The facial palsy was still present and the right arm was still weak. On the fifth day the face palsy was less, and on the tenth day face and arm paralysis had entirely disappeared. The speech was unintelligible although she was perfectly conscious. In three weeks there was a persistent difficulty in saying sentences which were intelligible throughout. The beginning of them would be intelligible and then the words would become jumbled together and incoherent. This was explained by the fact that the speaking and thinking centers became easily exhausted. It was two months before she regained full control of her speech. The wound healed by primary union. Examination now, sixteen months after the injury, showed no ill effects whatever. The skull defect was very firm. She had now no headaches nor eye defects, no weakness of facial or arm muscles, and her cerebration was as good as before the injury. This case illustrated the advantage of having an electrode present in head operations. Also the well-known fact that lacerations of important centers might heal perfectly and leave no ill effects. Also that the motor centers lay more in front of the fissure of Rolando than behind.

Dr. Samuel Lloyd had an experience with Jacksonian epilepsy some years ago which followed traumatism, and Dr. Hammond was asked to see. A cyst was found at the lower portion of the fissure of Rolando. The patient evidently had had hemorrhage which was followed by cystic degeneration around that area. This patient made a perfectly good recovery from the operation. Several days after, when making rounds, the nurse got things ready for dressing and he was informed that suddenly a hemorrhage came on. Dr. Lloyd hurried to the ward and found a profuse hemorrhage going on. He took down the external dressing and found that ordinary pressure would not control it. With his hands as they were he pushed his thumb into the lateral sinus, packed in iodoform gauze, carried the man to the operating room, cleaned up and repacked the wound. This man made a perfect recovery with no return of the Jacksonian epilepsy and without a suppuration of the wound. It was now eight or ten years since the operation and the patient had remained perfectly well.

Dr. Alexis V. Moschcowitz asked if it was not exceptionally rare to have attacks of Jacksonian epilepsy coming on so many days after fracture of the skull. From Dr. McWilliams's report one would expect to find paralysis of the face or what corresponded to that portion of the brain involved in the injury. It struck him as being particularly odd that typical attacks of Jacksonian epilepsy should come on so soon after a lacerating injury to the brain.

Dr. McWilliams answered that the patient had paralysis of the face and arm; the paralysis first appeared and then came on these attacks of Jacksonian epilepsy.

Dr. L. Pierce Clark, speaking in reference to the Faradic current and its application in such cases, said that two or three years ago he saw a case in Yonkers. This man had had an operation performed for some left-sided condition which was followed by Jacksonian fits and paralysis of the left arm and face. The inference was that some secondary lesion was present in the right motor area. An operation was undertaken on that side. There appeared a great deal of bulging, but probing the cortex revealed no abscess or other lesions whatever. The Faradic battery was applied, and the cortex stimulated and it was learned that the left face and arm did not move, but that the right did. This was an uncrossed case, a rare condition, of course, and it showed the importance of the Faradic battery.

Dr. Thomas P. Prout discussed the paper.

Nerve Bridging, with a Report of a Successful Case.—Dr. Alfred S. Taylor read this communication. To help the nerve ends to grow together various expedients had been used and might be classified as follows: (1) Neuroplasty, where one or both of the nerve ends were so split and turned over as to meet and bridge the gap. (2) Grafting or nerve-transplantation, where a section of nerve from the same or another individual, or even from one of the lower animals, was made to fill the gap by suturing its ends to those of the divided nerve. (3) Tubulization, where a tube was used to connect the two nerve ends to prevent the ingrowth of connective tissue during the development of the new nerve tissue which was to form the permanent bridge. (4) Suture *à distance* where a catgut suture was passed from one nerve end to the other several times, forming a framework between the two. With this was often combined one of the tubulization methods. (5) Resection of bone, where enough bone was removed to permit direct end-to-end suture of the nerve. (6) Lateral implantation of both proximal and distal stumps of the damaged nerve into a neighboring motor nerve. It was well established that materials interposed between the nerve ends acted only as guides which degenerated and were absorbed as the new nerve grew. Dr. Taylor reported a case representing the successful bridging of a 2 cm. gap in each of the roots of the brachial plexus, by means of a suture *à distance* combined with a modified tubulization due to the use of the Cargyle membrane. The case was a most favorable one because of the very excellent general condition, and the early age of the child. Nerve tissue bridged a gap at the rate of ¼ mm. per day. As a rule failure would follow any attempt to bridge a gap more than 4 cm. Authentic cases of nerve regeneration with return of motor power had been reported where the paralysis had continued for five, ten, fifteen, and even twenty-nine years before operation. The following was his summary: (1) The literature of nerve surgery was not well indexed. Case reports gave results in very general terms, often because of the difficulty of tracing cases and making systematic examinations over the long periods of time necessary. (2) Much experimental work was still necessary to determine the best technique for the solution of the various problems in nerve surgery. (3) Nerve defects could be bridged. Judging from the materials at hand, suture à distance offered the simplest and most successful method. (4) The younger the patient and the bet-

ter the general condition, the more hopeful was the result. (5) Results came only a long time after operation and depended for completeness upon massage, passive motion, electricity, etc. (6) Probabilities were against the bridging of gaps greater than 4 cm., although a few cases had been reported. (7) For defects larger than 4 cm. resection of bone or lateral implantation of nerve ends might be used. Good muscle power with bone deformity in an extremity was much to be preferred to complete or serious paralysis.

Dr. L. Pierce Clark confined his remarks to some experimental work in progress of completion. Some three years ago it occurred to him that to further substantiate the clinical advantages of end to side anastomosis in the human, experimental studies of the problem on animals would be very valuable. The condition of the experiments were to approximate those in man. The whole subject of repair in anastomosis was to be subjected to careful histological review. It was necessary in so delicate a structure as nerve tissue that any surgical procedure involving it should be conducted with the least possible traumatism. This would indicate the greatest care in the manipulation of the nerve and the use of such suture material as would inflict the least damage to nerve and sheath at the time of operation, and would finally be absorbed, leaving no foreign substance in or about the nerve. In the usual method of lateral anastomosis, the ingraft was held by two sutures of fine silk, the silk being passed transversely through the sheath of the nerve to be ingrafted. In doing this it was impossible not to include some nerve fibers, and when these sutures were tied the function of the fibers so included was permanently destroyed or impaired. The smaller the nerve the greater the chance of including the fibers and the greater the proportionate damage. The technique they followed was to make the usual slit into the nerve sheath. The edges of the slit were raised and a suture was passed from *without in*. This same needle was then passed through the sheath of the ingraft and finally through the opposite of the slit sheath from *within out*. On drawing the suture the ingraft was forced into the incision and by forceps the end might be adjusted and the suture tied. They used three kinds of suture, silk, kangaroo tendon, and rat-tail tendon. Rat-tail tendon was obtained in strands from four to six inches in length. It had a remarkable tensile strength, its surface was smooth and regular, and it was very pliable. It absorbed in from nine to fourteen days, sufficiently long for union to take place. The advantages of this method he summed up as follows: A minimum manipulation of the nerves to be united. The ingraft had but one suture through it. It was an absorbable suture which left no foreign material encapsulated. There was a tendency of the tied suture to draw the sheath over the ingraft. From a neurological standpoint there could be no doubt that the final result in clinical work was absolutely dependent upon the nicety of surgical technique, as had been shown in the treatment of different palsies.

Dr. Thomas P. Prout said he wished to emphasize the necessity of the after-treatment in these cases. He saw the other day a case of injury to the brachial plexus; a man had received an injury of the sixth root of that plexus and he had been operated upon by a surgeon of this city four months ago. The after-treatment had been neglected and the result was bad. As a matter of fact the operation would accomplish nothing except the approximation of the nerve ends unless one employed electricity, massage, and passive motion. He doubted very much the ability of the nerve to grow distally to the extent of two or three inches.

Dr. Dunlap pictured on the blackboard the results of the implantation of one nerve into another and showed that fibers did grow into the ingraft, and that there was such a possibility for certain pathways to exist. The sheaths did unite, and the fibers could, without any doubt, grow into the implanted nerve. Drawings of nerve fibers stained black with Weigert's stain were shown.

Dr. Charles E. Atwood said this was a very important subject, more so at present because of the fact that in New York City there were between two and three thousand cases of poliomyelitis, and a number of these cases would require orthopedic attention, with muscle and nerve implantation.

Dr. Charles E. Elsberg said that one should not lose hope if a number of months passed before the first signs of improvement were noted. He had had an interesting experience recently. Eight or nine months ago he did an anastomosis of the spinal accessory in a case of facial palsy. Treatment by electricity and massage was carried out without apparent improvement. The patient grew disgusted and did not appear until two months ago with a marked improvement, which began only during the last month. With regard to the technique, he said one should leave a little bit of tissue around the nerve and handle the nerve by means of it. In the case recorded, he left a little bit of muscle and so was enabled to handle the nerve without using forceps at all.

Dr. Taylor said that if they could do an anastomosis without any strain upon the sutures, almost any suture material would do, such as fine silk. Silk was absorbed; its fibers became infiltrated with leucocytes which caused it to disappear. If there was any tension upon the sutures, silk would not do. In 1903 the *British Medical Journal* reported a considerable amount of this work, and microscopical slides were shown demonstrating a proximal trunk actually split into a fork, one portion of the fibers running into it while the other ran down into the trunk.

The Clinical Significance of McBurney's Point.—Dr. Arnold Sturmdorf read this paper. He said that, regarding this, Dr. McBurney wrote as follows: "The exact locality of the greatest sensitiveness to pressure has seemed to me to be usually one of importance. Whatever may be the position of the healthy appendix as found in the deadhouse, and I am well aware that its position when uninflamed varies greatly, I have found in all my operations that it lay either thickened, shortened or adherent very close to its attachment to the cecum. This, of course, must in the early stages of the disease determine the seat of greatest pain on pressure, and I believe that in every case the seat of greatest pain, determined by the pressure of one finger, has been exactly between an inch and a half and two inches from the anterior superior spinous process of the ilium on a straight line drawn from that process to the umbilicus. This may appear to be an affectation of accuracy, but as far as my experience goes the observation is correct." Antedating the adoption of present-day methods, the introduction of McBurney's point marked an epoch and a phase in the evolution of their mastery over appendicitis; nevertheless, while it served to blaze the path through the mazes of earlier controversies it had proven an equally patent factor in leading to error and fruitless mutilation. McBurney's point, vested with pathognomonic dignity for almost two decades, must be relegated to the humble rank of a possible contributory diagnostic factor. While it was true today, as it was twenty years ago, that a typical McBurney's point might be present in a typical appendicitis, it was equally true that appendicitis might exist in the absence of a McBurney's point, and, most important, a typical McBurney's point might be present in the absence of appendiceal involvement. Much information of an empirical nature, gleaned from the observations of Ross, MacKenzie, Head, and others, on the distribution and character of the pain in visceral disease had not found general clinical utilization. Ross contended that in visceral disturbances pain or tenderness radiated along

the distribution of the somatic nerves springing from that segment of the cord which supplied the sympathetic fibers to the affected area. MacKenzie and Head defined certain areas which correspond to the cutaneous termination of the pain fibers springing from the cord segment involved by the disturbed viscus. These men had established one clinical fact, that any given point of pain might be either the direct expression of a contiguous disturbance or the transmitted manifestation of a distant lesion. In other words, an existing McBurney's point might represent the direct pain of a disturbance within its own area, or the reflected pain focus of a distant lesion. Head insisted upon the gentlest possible tactile exploration of the cutaneous surface, eliciting superficial areas of pain only; while McBurney's method, the direct pressure of one finger, of necessity elecited both superficial and deep-seated pain points at the same time. Therefore, it followed that there were two McBurny's points, one superficial, the other deep. The superficial pain point presented all the characteristics of Head's so-called "referred pain points" indicating a disturbance beyond the limits of their own area; while the deep or direct pain point, when present, would be found to indicate a local disturbance within its immediate vicinity.

Dr. Robert T. Morris said that for the most part McBurney's point served them. They did get a definite tenderness at that point in acute infections. It was also true that tenderness at McBurney's point might be reflected from the right side of the abdomen, but not from the right pelvis, a point that, so far as he knew, was not made by authors. If there was an inflammation of the appendix they had a hyperesthesia over the border of the right lumbar plexus, but not of the left one. If there was an inflammation of the right oviduct both lumbar plexuses were hyperesthetic together, and not singly, so far as his observations went.

Dr. Samuel Lloyd said that he believed McBurney's point did much harm and he himself placed absolutely no dependence upon it.

Dr. Sturmdorf closed the discussion.

Election of Officers.—*Chairman*, Dr. Charles H. Peck; *Secretary*, Dr. W. A. Downes.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held December 26, 1907.

Dr. Herman J. Boldt, Chairman Pro Tem.

A Case of Pubiotomy.—Dr. Sidney D. Jacobson presented a patient who was admitted to the hospital September 17, 1907. She was of medium height and weight and showed evidences of rickets occurring in early life. She was forty-two years old and a primipara. She had been in labor for thirty-six hours and her pains when admitted came on every three minutes. The uterus was apparently the size of full term. The fetus occupied the right dorso-anterior position and presenting with the head. The head above the pelvic brim was quite movable and Hofmeier's method of making it engage was unsuccessful. The fetal heart sounds were somewhat muffled, with a rate of 176. The vulva was edematous and the vagina hot, dry, and swollen. The cervix was open to the extent of admitting three fingers. Attempts at manual dilatation were unsuccessful. The bag of waters had ruptured some hours prior to admission and had drained away. The child's head could not be made to enter and engage in the pelvic ring, being entirely above the brim. It approximated the position R. O. A., but would not retain it. On examination of the pelvis it was decided that the patient had a generally contracted rachitic pelvis, with a true conjugate estimated to be three and a quarter inches long. Natural delivery was impossible. High forceps would have been fruitless. Perforation of the child's head was unjustifiable, and cesarean section was contraindicated because the uterus was already, at least theoretically, infected and would have given a live child but a dead mother, so pubiotomy was the logical operation done. This was done on the left side by the subcutaneous method of Döderlein. After the bone had been divided with the Gigli saw, the child was delivered by aid of high forceps in good condition. The hemorrhage was considerable. The placenta was removed manually. The bladder escaped injury. Intravenous infusion was given. There were lateral tears in the cervix of medium severity. The vagina was torn in its left upper portion and the cut ends of the bone separated about one and a half inches and could be felt by the examining finger. No sutures were introduced. The uterus and vagina were packed with sterile gauze. To prevent too wide a separation of the cut ends of the pubic bone, three strips of adhesive plaster two and a half inches wide and closed in front by attached tapes were placed around the pelvis before the section and tied securely. Much stress was laid upon the important point of keeping the patient's toes turned inwards during the bone section. It was astonishing how well one could then control the amount of bone separation by the degree of inversion of the feet. The feet were tied together for one week in this position and this, besides the three adhesive strips around the pelvis, was the only means used to partly immobilize the pelvis. The patient made a smooth recovery. She nursed her baby. Sixteen days after the operation the patient left her bed. On the eighteenth day she left the hospital and on the twenty-first day she was met on the street pushing her baby carriage. Her walking was perfectly natural. He expressed the hope that pubiotomy might find its way into more general favor.

Dr. Achilles Rose protested against the name pubiotomy; he considered this a barbarous term; it was a hybrid that should not be used in scientific literature, because it was unscientific.

Report of a Case of Interstitial Pregnancy.—Dr. Herman Grad reported a case of pregnancy occurring in the horn of the uterus and the uterine end of the Fallopian tube. This was presented in order to bring about a discussion of this form of pregnancy, which was not entirely ectopic nor strictly speaking intrauterine. He believed the term "apical pregnancy" would more clearly define these cases. In this type of pregnancy the impregnated ovum began to develop partly in the uterine end of the tube and partly in the horn of the uterus. As pregnancy advanced the case might become the ectopic type or an intrauterine one, depending upon the developing ovum encroaching more upon the tubal or uterine side of its bed. If the tube was encroached upon, the case might terminate in an ectopic gestation; if the ovum grew in the direction of the uterus, it might become an intrauterine one, and might terminate in normal labor. Many of these cases necessarily escaped diagnosis and detection. It was only in the cases where the early months of pregnancy were marked by severe pain and an examination was made that the condition of apical pregnancy was diagnosticated. Many of these cases terminated in miscarriage and were never diagnosed. The case reported taught that, given a case of pregnancy presenting abnormal and unusual symptoms, in making a diagnosis one must bear in mind not only the possibility of an ectopic gestation and pathological states of intrauterine pregnancy, but also a class of pregnancies occurring in the horn of a normal uterus, for which he suggested the term of "apical pregnancy."

Dr. S. Marx asked if the Section thought it would be proper to have the report of this case go on record as one of interstitial pregnancy. This report recalled to his mind a number of cases that he had seen, and one in

particular that was reported by a colleague in which the fetus escaped into the uterine cavity and the secundines were still in the tube. It was proven that primarily they were dealing with a tubal pregnancy, with the escape of the fetus into the uterine cavity. Soon after a similar case was seen presenting the same phenomena. The fetus was found to be hanging into the uterine cavity and the secundines were still in the tube. Cases of interstitial pregnancies were fraught with terrible accidents, so much so that one could hardly believe that they were dealing with one without the occurrence of fearful results. He reported the case of a young woman who was pregnant about three months and who bled continuously. The physician in charge wisely considered the induction of abortion; divulsion was performed with a steel dilator and the organ packed with gauze. The day following, when he expected to repack her, when he withdrew the gauze he found intestines in the vagina. She was sent to the hospital. Dr. Marx did not believe that so much intestine could present in the vagina. The amount of destruction of that fetus was as though it had been blown up by dynamite. The destruction occurring in interstitial pregnancies was very great.

Dr. A. Brothers said that he too would hesitate to accept the diagnosis of interstitial pregnancy as correct. He had had one experience during the past year, an unusual case in which there was no question that the fetal implantation took place in one cavity at the *cornus uteri*. He would not consider that a case of interstitial pregnancy, but an impregnation in one horn of the uterus. Some years ago, when the use of electricity was much in vogue, in 1888, he had a case of tubouterine pregnancy; with the finger he could feel the ovum protruding into the uterine cavity.

Dr. H. Grad said that the case was one of tubouterine pregnancy. Apical pregnancy he believed should be the term to use. The ovum started in the horn of the uterus and dilated that portion of it, and felt like a fibroid. He did not believe it was a case of true interstitial pregnancy. If it had gone on it might have terminated in true labor. The uterine cavity was empty. The fetus broke through and came away per vaginam. It was not a pregnancy in the tube; it was a case of pregnancy occurring in the horn of the uterus.

Abdominal Extirpation of Myomatous Uterus for Life Endangering Bleeding.—Dr. Herman J. Boldt reported the instance of a woman who had been bleeding profusely for a period of three months. She alleged that she had been curetted several times, the diagnosis of an incomplete abortion having been made. When seen her hemoglobin was reduced to 20 per cent. Vaginal tamponing was useless. The temperature varied from 101° to 103° F., which was caused by a septic process in the submucous tumor. As demonstrated on the specimen, the only way to cope successfully with the uterus, which was invaded by an intimately adherent submucous tumor, and a subperitoneal tumor, was to do a radical operation. The abdominal route was resorted to because of the very low condition of the patient, although it probably could have been done successfully by the vaginal route, despite the fact that the tumor reached nearly to the umbilicus. Yet by selecting the vaginal route the operation would have required more time, and the object was to operate as rapidly as possible. The time consumed was a little less than twenty minutes. An uninterrupted convalescence ensued.

Myoma of the Uterus; Myomectomy Done as a Preventive for Threatened Abortion.—Dr. Herman J. Boldt said that after an extensive search of the literature he had not been able to find another instance for which a deliberate excision of a myoma was done with the view of perhaps preventing an impending abortion. The case was therefore unique so far as he could ascertain. The patient was thirty years old, had been married three months, and consulted him on June 11, 1907. Her last menstruation occurred on April 4. For the last five years she had had pain in the lower left abdomen. On June 5 she commenced to spot and consulted a physician, who informed her that she had a tumor which required operation. The spotting continued until June 10, when she consulted Dr. Boldt as to the necessity of an operation. Examination showed the presence of a fairly large myoma in the lower segment of the uterus, on its anterior surface, complicating a pregnancy at about the third month, judging from the size of the uterus. The woman being very anxious to have a child, the advice was given not to have the gestation interrupted, but to enter a hospital near the termination of the gestation period and then, in case the myoma was an impediment to delivery, have a cesarean section done. On June 19 she again consulted Dr. Boldt complaining of labor-like pain and a return of the spotting. The occurrence of an abortion was imminent. It was believed by him that the cause of the impending abortion was due to the pressure that the myoma exerted. She was advised to enter the hospital at once and be operated upon. The operation he proposed to do was a myomectomy; this might perhaps retain the fetus for her by relieving her of the tumor pressure. She was given at the time a dose of morphine to stop the pain and then she went to the hospital. Operation was done on June 20. The position of the tumor practically divided the uterus into two halves. The neoplasm dipped deeply into the myometrium, as might be seen in the specimen. Immediately after enucleation of the growth, it was evident to all who witnessed the operation that the uterus began to assume its normal configuration, and by the time that the wound had been sutured the shape of the organ was normal. For the first week after operation morphine was administered in sufficient quantity to prevent the pains of labor. The woman made an excellent recovery. She was examined by Dr. Boldt December 26 and was found to be in perfect condition. Being in poor circumstances, she was advised to enter a maternity hospital to be confined.

Dr. A. Brothers referred to a case that he had presented to the New York Obstetrical Society two years ago. This woman had visited his office with her husband and was willing to submit to operation provided she had a living child. She was taken to the hospital, where Dr. Brothers removed five tumors varying in size from a cocoanut to a walnut, and some being pedunculated. She was under observation for three weeks, when she left the hospital with her pregnancy uninterrupted. She went to term and was delivered of a child. The indications were not those of a threatened abortion, but signs of it might have been presented at any time.

Dr. James N. West thought the men who reported these cases should be congratulated upon the successful outcome. Most would think that instead of preventing an abortion it would precipitate it. Dr. Duncan Abbott removed several tumors with the idea of preserving the fetus. This woman went to term and was delivered of a healthy child. Dr. West said that he had had thirty-three abdominal myomectomies and many of them were not in condition to become pregnant. Out of that number there were three that became pregnant and gave birth to living children at term. In one of these cases he removed sixteen tumors.

Dr. S. Marx thought the interesting part of this discussion was the success that attended the myomectomies. That was a clear indication for operation, but there were so many cases of uterine rupture on record following this operation that he asked the chairman, Dr. Boldt, to report the progress of his case at the next meeting.

Dr. A. Ernest Gallant and Dr. Achilles Rose discussed the specimen.

[In a letter, dated December 30, Dr. Boldt stated

to the reporter that the house physician of the Sloane Maternity had just informed him that this woman had been delivered of an eight and a half pound child, with normal labor, terminated with low forceps.]

The Prophylaxis and Treatment of Prolapse of the Uterus.—Dr. James N. West read this paper. He said that with the increased development of the brain which comparative ethnologists showed to have taken place in the civilized nations, and the consequent increase in the size of the fetal head, there had been unfortunately no corresponding development of the pelvis to accommodate them. On the contrary, the habits of women in civilized communities were such as to add to the difficulties of parturition caused by the large heads, those of small and more or less contracted pelves. To these obstacles to labor was further added that of the increase in rigidity of the muscles as well as of the articulations of the pelvic bones due to late child bearing. Nature tended to hold to a certain type and measure, for the larger the fetal head and the more imperfect the maternal mechanism of reproduction, the greater would be the fetal as well as the maternal mortality in parturition, and also more frequent would be the maternal injuries and secondarily the establishment of pathological conditions which would prevent conception. The future promised no cessation of these difficulties, but rather their increase. Among the disabling and painful conditions which might be traced chiefly to the injuries of parturition, prolapse of the uterus was one of the most striking and most difficult to cure. It was as a rule so very much easier to arrest a prolapse in its early stages and to prevent its occurrence than to cure it when once established, that it was chiefly his hope of doing some good by calling attention to this fact that had tempted him to present this subject. He then presented in brief his conception of the forces which maintained the uterus in its normal position. There were two sets of direct supports, first, those which suspended the uterus and other pelvic organs within the pelvis, and secondly, the muscles and fascia which closed the pelvic outlet and acted as a buttress or reinforcement of the intrapelvic supports. It was not necessary that there should be an actual solution of continuity in any of the structures constituting the ordinary supports of the pelvic organs, but a superimposed weight might be too great for their natural strength, or a loss of tone in the structures themselves might be such as to cause them to fail in their function of supporting organs of normal weight. He called attention to the great importance of an appreciation of these supporting structures and of the connective tissue especially. He quoted Savage as saying that a permanent cure of uterine prolapse depended chiefly upon the elastic qualities of subperitoneal pelvic connective tissue. The latter always retained its relations with the displaced organs as well as with the pelvic vessels. Owing to the slow progress of the prolapse, the connective tissue yielded to an enormous extent; but the fibro-elastic elements of its structure would very often enable it to return eventually to its normal condition if relieved from the weight of its prolapse. The conditions which favored overstretching of the pelvic connective tissue and prolapse were: (1) A solution of continuity of greater or less degree of the muscles and fascia of the pelvic floor. (2) Conditions which caused loss of tone or resiliency, as inflammatory conditions, the presence of necrotic material in the uterus, obstructions to the local circulation, and constitutional conditions. (3) Those which caused an increase of weight in the pelvic organs beyond which their supports were intended to bear, as tumors or subinvolution. (4) Alterations in the position of the uterus in regard to the direction of its long axis and consequent alteration of the effect of intraabdominal pressure. All or any of these conditions might exist in combination. The axis of the vagina was such that intrapelvic pressure was at right angles to it, and its full force was met at every point by the powerful levator ani muscle and fascia and muscles of the perineum. When these structures were lacerated, the direction of the intra-abdominal force became more or less straight instead of oblique, and, the lower supports being removed, the whole strain fell upon the intrapelvic ligaments and connective tissue. When these began to stretch and give way, the cervix swung further in towards the pubes and the fundus backwards and the first long stride toward procidentia began. The first important step in the prophylaxis in such cases was early and thorough repair of the perineum. Dr. West said he was convinced that no common operation was so little understood and met with such uniform failure as that of repair of the perineum after laceration. He believed that every case of abortion should be curetted, the uterus thoroughly washed out and painted with pure carbolic so soon as it was positively ascertained that the abortion was inevitable and the cervix had been dilated. Under the head of obstructions, laceration of the cervix was a most frequent cause, also inducing a great number of cases of endometritis fungosa. Such lacerations as were of sufficient extent to cause symptoms should be repaired within the first six months and in most instances should be accompanied by a light curettage. The constitutional and local treatment should not be neglected. Retroversion was almost always a necessary stage in the course of the formation of prolapse which led to procidentia. A very large proportion of the retroversions following labor or abortion were easily preventable. Dr. West found the most frequent cause of retroversion to be due to the uterus having settled back into the hollow of the sacrum after labor. Such a displacement should be corrected and the uterus held forward by artificial supports. Every woman after confinement at term or abortion should be examined several times at intervals of about five days to ascertain whether the uterus was coming to its proper position or not. This was one of the most fruitful fields of prophylaxis against prolapse and procidentia. In the aged and infirm and in those with certain complicating diseases those far beyond the reach of operative interference must of necessity be treated in a palliative way, and resort must be had to decubitus, pessaries, balls, etc. The cases that were operable had called forth the greatest ingenuity and the most strenuous endeavor for their relief. An absolutely satisfactory operative procedure had not yet been devised. Dr. West then presented some of the more radical measures as given by Döderlein and Krönig. Some of the most miserable human beings Dr. West had ever seen had been women upon whom the removal of the vagina, uterus, and ovaries had been done for prolapse. In the bad cases Dr. West advocated a long preparation by rest in bed with the foot elevated, and copious astringent hot douches, scientific massage, a good and nutritious diet, tonics, etc. Under such a treatment ulcers of the vagina or cervix would heal, involution would take place in all the hypertrophied structures, and the pelvic connective tissue would in a large measure regain its tone and the organs their natural relations. When the maximum amount of benefit had been attained, the patient was ready for operation. In most cases the levator ani and perineæ were carefully repaired, and the anterior wall had a radical operation done upon it. Often the cervix was amputated and a ventral fixation of the uterus made. Some variations were sometimes made, but it had been his good fortune to have cured, absolutely, a fair number of very bad cases of complete procidentia, without using any of the destructive deforming operations. He made an appeal for a more thorough prophylaxis and a rational operative procedure which should have for its chief aim a restoration to natural conditions.

Dr. Samuel W. Bandler emphasized the necessity for

prophylaxis, and said that subinvolution after labor required, not two or three weeks, but perhaps six months' care on the part of the physician. Before the patient was restored to normal as regarded the nervous system, the abdominal and pelvic organs, etc., months would be required and not weeks. A type he called attention to was the neurasthenic, one with lax abdominal walls. Attention should be paid not only to the ligaments of the pelvis, but of the entire body. The normal uterus was a fairly horizontal one and was held in place by six ligaments, which he demonstrated on the blackboard. The use of the pessary was of the greatest value and should be used for four weeks; this was a long stride in the prevention of the descent of the uterus. Associated with these cases one found a general ptosis, *i.e.* a gastroptosis, an enteroptosis, movable kidney, etc. In such conditions care was demanded for weeks, months and even years, with the use of the pessary, administration of ergot, proper food and exercise, baths, and doing all possible to get a good circulation.

Dr. A. Ernest Gallant and Dr. Sidney D. Jacobson discussed the paper.

Dr. West closed the discussion.

The Management of Febrile Conditions after Abortion and Labor.—Dr. Abram Brothers read this paper. He said that opinions varied greatly as to the bacteriology of the uterine interior after delivery. Some observers told them the uterine discharge was sterile in from 64 to 100 per cent. of the cases after delivery; others in 0 to 36 per cent. (Little). As to treatment, the same diversity of opinion existed. In spite of this, institutional statistics, which showed a mortality fifty years ago of 20 to 30 per cent., were now reduced to one death in 1,000 or less. On the other hand, the mortality in private practice, especially in the tenement districts, was the same as it was a quarter of a century ago. While occasionally autoinfection was responsible for sepsis, there should be no let-up in holding the midwife or accoucheur strictly to account until private statistics showed the same low rate of puerperal infection that they got in institutions. Sapremia after abortion could be treated more thoroughly with the curette than when the same condition occurred at full term. Still after abortion (especially the criminal variety) fevers might be also due to bacteriemia, parametric exudates, purulent collections in the Fallopian tubes or peritoneal cavity (usually in Douglas' cul-de-sac), occasionally to necrotic or suppurating fibroids, and to varying grades of peritonitis. Often several of these conditions were combined in the same case. The puerperal fevers proper were to-day divided into two main groups, the toxemias and the bacteriemias. For clinical purposes he had studied these cases during the past twenty or more years under four heads, as follows:

1. Fever due to retention of infected placenta débris or blood clots. These cases regularly got well after cleaning the uterus of placental débris.

2. Fever due to pelvic inflammation. These were the cases with exudates and might be associated with or follow the first group. Unless there was anything in the uterine cavity they should be left severely alone, and, unless the parametric exudate broke down and formed pus, these patients regularly got well.

3. Fever due to bacteriemia (septicemia). In this group (and the next) the blood and lymph systems were saturated to a greater or less degree with the bacteria themselves and not with their toxins. Before delivery such septic cases regularly died and probably nothing short of a timely cesarean section and hysterectomy offered them any hope. He had not had good results from hysterectomy in pure bacteriemia nor (in one case) from the ligation of the ovarian and internal iliac veins where pelvic thrombosis was diagnosticated. Opsonic vaccine and antistreptococcic serum had so far not proven of great avail. Neither had saline or chemical intravenous infusions proven of much benefit. These patients should be freely stimulated, nourished and supported, and their chances under these methods seemed about equal with those following the operative methods for their relief so far discovered. An exception might be made to the gonorrheal cases, especially with pus foci in the tubes or peritoneal cavity. Phlegmasia alba dolens was also included in this group, although it represented a mild disease from which the patients regularly got well under simple rest.

4 Fevers due to general peritonitis. These cases presented the worst kind of prognosis, especially the fulminating types. They presented the same appalling picture familiar to abdominal surgeons after some infections. Unless in the earliest stages or with uterine abscess, he failed to see any benefit from hysterectomy. Cyrille Jeannin had published 121 cases of general puerperal peritonitis subjected to surgical treatment, with 60 recoveries and 61 deaths. Therefore, it was fair to assume that, in proper hands, a laparotomy was proper in cases of puerperal peritonitis, provided that the septic process had not already invaded the lungs or other distant organs. Still, he had never known cases, perhaps of a less virulent type, to occasionally subside spontaneously and the patients to get well. Cases with local suppuration, whether the pus pocket lay between the coils of intestines or in the pouch of Douglas, always required operation.

Resolution.—It was moved and seconded that, because of the importance of Dr. Brothers' paper and the lateness of the hour, Dr. Brothers be requested to prepare a brief abstract of the paper and present it at the next meeting, in order that a proper discussion might take place. This was unanimously carried.

Philadelphia Neurological Society.

At a stated meeting held November 26 Dr. Spencer M Free of Dubois, Pa., presented three patients illustrating the types of "Acute Anterior Poliomyelitis" observed during the recent epidemic of the disease. In one there had been involvement of all four extremities, with almost complete recovery. In the others the improvement had been less complete, and there were varying degrees of disability, in upper as well as in lower extremities. The palsy did not appear at the same period of the disease in all cases, in some instances being an initial phenomenon and in others not becoming evident till later. Dr. C. S. Potts presented "A Case of Acute Anterior Poliomyelitis with Involvement of the Muscles of the Chest." There was an extraordinary degree of atrophy of all of the muscles, with marked weakness, but without winging of the scapulæ. Dr. S. D. Ingham presented "A Case of an Old Acute Anterior Poliomyelitis followed by Atrophy of the Muscles of the Hand and Face." Dr. Alfred Gordon presented "A Case of Polioencephalitis Inferior." The patient was a woman who exhibited mutism, together with atrophy of the tongue, fibrillary tremor, and reaction of degeneration. Dr. T. H. Weisenburg presented "A Case of Hereditary External Ophthalmoplegia." The patient was a girl about seven years old, whose mother and grandmother had presented a similar condition. There was bilateral ptosis and complete inability to move the eyes in any direction. Dr. Wharton Sinkler presented a communication entitled "The Poliomyelitis Epidemic in Philadelphia." He showed by figures collected from several of the hospitals that there had been a marked increase in the number of cases of acute anterior poliomyelitis treated during the past summer. He had many years ago pointed out that the disease is peculiarly one of the warm season, and this observation has been confirmed repeatedly. Epidemics have been reported on several occasions. The disease must from the evidence be con-

sidered an infectious one, although the actual etiological factor has not been demonstrated. Dr. SPENCER M. FREE of Dubois, Pa., presented by invitation a communication entitled "The Poliomyelitis Epidemic in the State." He gave a description of the mode of onset and of the symptoms observed in the cases in his town and county. There had been several deaths, but no post-mortem examination. Dr. R. S. MCCOMBS read "A Study of the Cases of Acute Anterior Poliomyelitis at the Children's Hospital." He noted the increased number of cases, particularly of recent origin, many of them coming from a limited section of the city, although some came also from distant and widely separated points.

COLLEGE OF PHYSICIANS OF PHILADELPHIA: SECTION ON OTOLOGY AND LARYNGOLOGY.

AT a stated meeting held November 20, Dr. G. HUDSON MAKUEN presented a larynx from a three months' old infant in whom death had occurred from stenosis from an undetermined cause. Without premonitory symptoms dyspnea and cyanosis made their appearance, from which intubation failed to afford relief. Tracheotomy was advised but the parents withheld assent. The thymus gland was enlarged. Among the possible causes for the condition suggested were new growth, thymic asthma, or lymphatism, hernia of a ventricular band, aspiration of the epiglottis. Dr. CHEVALIER JACKSON of Pittsburg delivered by invitation an address on "The Bronchoscope in the Removal of Foreign Bodies from the Upper Air-passages." Dr. Jackson demonstrated the technique of introducing the instruments employed and related a number of cases in which foreign bodies in the air-passages were discovered and subsequently removed with the aid of the bronchoscope. He also discussed the possibilities of this mode of diagnosis in the recognition of ulceration in the trachea and bronchial tubes and of conditions of the stomach by means of the gastroscope. Cocaine anesthesia is sufficient for purposes of examination, but chloroform anesthesia is necessary when operation is required. Dr. JOHN W. ROYCE pointed out the necessity for having absolute control of the patient subjected to the examination or operation, so that his head and neck are adjusted to the various manipulations of the operator, as the instruments employed are straight. The assistant must anticipate every movement of the operator so that no obstruction is encountered at any point. Dr. GEORGE MCCLELLAN discussed the anatomical relations of the parts concerned, while Dr. JOHN H. GIBBON and Dr. WM. L. RODMAN discussed the subject from the surgical standpoint, and Dr. JAMES C. WILSON and Dr. JAMES TYSON discussed it from the medical standpoint. Dr. W. M. LATE COPLIN presented a consideration of the pathology of the structures concerned, and Dr. G. E. PFAHLER spoke of the application of the *x*-ray in the diagnosis of the conditions under consideration.

CLASSIFICATION OF CASES OF APPENDICITIS.*

BY JOHN J. McGRATH, M.D.,

NEW YORK.

PROFESSOR OF OPERATIVE SURGERY AT THE NEW YORK POST-GRADUATE SCHOOL AND HOSPITAL; VISITING SURGEON TO THE HARLEM AND COLUMBUS HOSPITALS; CONSULTING SURGEON TO THE NEW YORK FOUNDLING AND THE BRATTLEBORO MEMORIAL HOSPITALS.

IN a case of suspected appendicitis it is not sufficient to make a general diagnosis of inflammation of the appendix. It is of the greatest importance to go a step further and diagnosticate the exact character of the lesion in order to determine the proper method of treatment suitable to the individual case. The question of immediate operation or the propriety of temporizing depends entirely upon the nature of the attack—upon the exact pathological condition that we have to deal with.

There are three different clinical forms of appendicitis which are to be considered, and these may be described in brief as follows: First, the simple catarrhal, which may be either acute or chronic; second, that form which is associated with a circumscribed abscess; and third, that which is characterized by acute gangrene of the organ, without the formation of limiting peritoneal adhesions, and therefore necessarily associated with more or less peritoneal infection. We encounter occasional cases of tuberculous appendicitis, but a consideration of this form of disease may be disregarded at present, so as not to confuse the more important features that it is especially desirable to bring out.

The simple catarrhal form of appendicitis, the non-suppurative, may be either acute or chronic.

In the acute cases the appendix is found more or less enlarged, swollen, congested, the small superficial veins in the serous coat injected and plainly visible; the wall of the organ is infiltrated with inflammatory products and mucous or mucopurulent material is found in the lumen. The lining mucous membrane is red and swollen and often shows ulcerated areas, and the lumen of the organ may be more or less narrowed or obliterated through the swelling of the mucous layer. There may be flakes or patches of fresh fibrin around about the appendix agglutinating it to the adjacent peritoneal structures. The mesoappendix is thickened and its blood-vessels injected, and it may be adherent to the adjacent peritoneal structures. After the acute attack has subsided, and especially if there have been several preceding attacks, there may remain organized connective tissue bands that fix the appendix to the adjacent peritoneal organs and surfaces, limit its mobility, and cause kinking or torsion of the organ. Healing of ulcerated areas in the mucous membrane may leave the lumen strictured or the entire lumen may have become narrowed or obliterated through the inflammatory thickening of the wall of the organ, and one or more fecal concretions may be left remaining within the appendix; thus, when these patients with so-called simple acute catarrhal appendicitis escape operation and apparently recover, many are left with a dangerously damaged appendix, one readily susceptible upon slight provocation to renewed attacks.

In the chronic cases the appendix may exhibit but little gross change. It may be simply thickened or its lumen may be obliterated, due to a gradual increase of the connective tissue elements of its wall. The veins in the serous coat are injected and plainly visible. The lumen may be strictured and the mucous lining membrane show areas of ulceration. A fecal concretion may be contained within. There may be present adhesions that kink or twist the appendix, limiting its mobility and fixing it to the adjacent peritoneal parts—at times it is found adherent to the right tube and ovary.

These so-called catarrhal cases, acute and chronic, are characterized by the absence of perforation, gangrene, or abscess formation.

In the second group of cases, the abscess cases, we find the inflamed appendix, enclosed in an abscess cavity containing a varying quantity of foul-smelling pus. The walls of the abscess are formed by the adjacent peritoneal surfaces, coils of small intestine, cecum, and omentum, held together by recent inflammatory adhesions. After the adhesions have been broken up and the abscess opened, the appendix, intensely congested and swollen and maybe or may be not perforated or presenting areas of gangrene, is found adherent to the wall of the cecum upon its outer or its inner side, or curled up underneath the head of the cecum and coils of small intestine, its tip pointing upward, or else it may reach down into the pelvis, where it may be adherent to the side of the bladder or involved in an inflammatory mass made up of the right tube and ovary. If the appendix is already perforated the opening may be seen, usually nearer the free end, the concretion having already escaped or else presenting at the opening in the appendix. Occasionally we find the appendix still intact and with a concretion easily felt within it. The mesoappendix and adjacent omentum are found intensely congested, red, thickened, and stiff and brawny. The abscess is situated according to the position of the appendix to the outer or to the inner side of or underneath the head of the cecum, or extending down into the pelvis alongside of the bladder. In these abscess cases the limiting adhesions may break down, maybe through transporting patients from home to hospital, and as a result we get leakage of the pus, with a general or progressive peritonitis.

The third group of cases is marked by the absence of protective peritoneal adhesions and by the

*Read before the Waterbury (Conn.) Medical Society October 14, and the Middlesex (New Jersey) County Society October 15, 1907.

necrotic character of the lesion. The appendix is found congested, swollen, thickened, red, with gangrenous areas of greenish-black and usually already perforated, or in some cases where the process is more pronounced and very rapid, the entire appendix may have become gangrenous and present the green-black appearance which is characteristic of that condition. There may be patches of fresh fibrin upon the adjacent peritoneal surfaces, but no effort at adhesions or walling-off of the diseased appendix has been made—the process has been too quick—more like an acute gangrene due to interference with the circulation, to thrombosis and occlusion of the blood-vessels of the appendix, than to an inflammatory process. Primarily the process may have been inflammatory, but the destructive element entirely overshadows the inflammatory and the necrosis occurs so quickly, so abruptly, that there is not sufficient time for protecting adhesions and an abscess to be formed. Some of these cases show complete absence of any inflammatory element whatever, and the appendix is found as a thin-walled, flaccid, black, gangrenous tube, sloughed throughout its entire length, clear up to the cecum. Several cases have been seen by the writer where this condition obtained—one with the green-black sloughed appendix completely severed from the cecum. Probably these conditions are the result of infectious thrombosis of the veins that drain the appendix, or else of interference with the circulation, due to compression of the engorged, swollen organ within its unyielding serous outer envelope or around a concretion contained within its lumen. In some cases the adjoining part of the cecum shows a similar gangrenous appearance. The blood-vessels of the appendix are found blocked with septic thrombi. When the abdomen is opened there escapes a varying amount of serous, turbid, sticky fluid. If diagnosticated early and operated upon promptly we may find the process not so far advanced, the appendix still unperforated and with little fluid in the peritoneal cavity.

Diagnosis.—The question is whether it is possible to differentiate between these several conditions clinically. I believe that it is in most, if not in all, cases, and this definite, accurate diagnosis is of the greatest practical importance, in the first place, in order to determine the proper method of treatment, and, in the second, in order to arrive at a proper prognosis as to the outcome of the case. The mortality from appendicitis is due to failure to differentiate and to recognize the bad cases sufficiently early.

In the first group of cases we have to do with a catarrhal inflammation which may be either acute or chronic.

Chronic catarrhal appendicitis is not an uncommon condition. It is probably not always a distinctly localized inflammation of the appendix limited to that organ alone, but oftentimes rather part of a general disturbance of the intestinal canal—the appendix giving mild symptoms every time that a greater degree of congestion of the organ causes it to swell within its serous envelope, with a resultant narrowing of its lumen, especially its mouth, and interference with proper drainage, discharge of its secretions. The chief symptom in this set of cases is the more or less constant feeling of discomfort associated with occasional attacks of more acute pain referred to the region of the appendix. The more acute attacks are as a rule coincident with a more pronounced, acute general disturbance of the gastrointestinal canal, often due to indiscretions in diet, and varying in degree of severity up to a typical attack of acute appendicitis. Examination even during the intervals of relative quiescence reveals a point of localized tenderness over the site of the appendix and oftentimes the appendix may be plainly recognized upon palpation as a tender tube. To facilitate palpation of the appendix the patient, lying upon the back, is instructed to raise the right thigh with the leg extended at the knee. This puts the psoas muscle on the stretch, and using this as a guide or landmark the appendix can in many cases be felt to the outer side of the muscle and identified by the tenderness elicited when it is rolled under the examining finger.

The acute catarrhal condition is, in many instances, simply an exacerbation of a chronic appendicitis and often accompanies an attack of gastrointestinal disturbance following the ingestion of some unusual form of food that has disagreed with the patient. We have the history of gastric disturbance and pain in the abdomen, which gradually becomes localized in the region of the appendix. With the settling of the pain in the appendix the bowels as a rule become constipated. This is an important symptom and in marked contrast to the diarrhea which is so characteristic of the ordinary attack of cholera morbus. There is a moderate elevation of temperature, 100° to 101°, and moderate acceleration of the pulse rate, 90 to 100. The patient does not look especially sick and lies upon the back with the right thigh and knee flexed. Upon examination and pressure at McBurney's point tenderness is elicited. As a rule this tenderness is distinctly localized. Pressure upon any other part of the abdomen is not associated with pain except in some few cases and then the pain is referred to the region of the appendix. The right rectus muscle is found rigid and resists the effort to palpate the right iliac fossa. There is no tumor to be felt. The belly is usually not markedly distended. If these acute catarrhal cases are seen early and placed upon proper treatment, the symptoms often subside in a few days and the attack stops short of suppuration. Still, upon the other hand, in spite of prompt and proper treatment some of them go on to suppuration and abscess formation and perforation or to sudden gangrene; hence the necessity, in the absence of operation, of carefully watching them for any sign of danger.

In the second group of cases, the abscess cases, we have the history of the attack beginning as described in the preceding paragraphs and lasting several days with the symptoms that have already been mentioned in the first set of cases, but the symptoms do not subside, they persist. The temperature goes higher and the pulse becomes more accelerated, although in occasional cases the temperature and pulse rate vary but slightly or not at all from the normal, and the constipation continues. Finally, after several days, upon palpation of the abdomen a tender tumor, occupying the iliac fossa, may be made out, indicating that an abscess has been formed. It will be noted that other parts of the abdomen remain fairly free from tenderness. In some of these cases the general symptoms that mark the early period of the disease and precede the formation of the abscess are so mild as to be overlooked or only brought out by careful investigation by the examining physician.

The adhesions that enclose the abscess may break down and as a result of leakage we may get a gen-

eral peritoneal infection, or new localized abscesses may form, each succeeding one connecting with the other—progressive peritonitis. These accidents give their own characteristic symptoms.

The third variety, the fulminating form, is the real deadly variety of appendicitis, and deadly because of the suddenness of its onset and meager symptoms and of its destructive character and the virulence of the infection. Many of the cases are unrecognized until too late for successful surgical treatment.

These patients may give a history of previous attacks or they may have been complaining of indefinite abdominal symptoms for several days, or they may be attacked without any warning whatever—may be suddenly awakened in the night with intense pain in the abdomen. The pain at first may not be referred to the region of the appendix but it does gradually become localized there.

Examination fails to reveal the presence of a tumor in the iliac fossa. The muscles of the abdomen are held rigid and pressure over the appendix elicits marked tenderness. The abdomen is distended. These patients have an anxious, sick look which is characteristic. Temperature is irregular, usually not elevated at first. Pulse is accelerated, and later, as the disease progresses, out of proportion to the temperature. As the disease progresses the rapidity of the pulse is a good indication of the degree of sepsis, peritoneal absorption, but is not infallible. We may have acute gangrene of the appendix with but little or no acceleration of the pulse, or even with diminished frequency of the pulse rate. In fact a low temperature and slow pulse, with distinct local signs of appendicitis, are characteristic of this form of appendicitis. The tongue is dry and coated. There are nausea, retching and vomiting. Constipation is marked and there may not even be gas expelled. This symptom of obstinate constipation is indicative of this variety of appendicitis; it is reflex in its origin and represents nature's effort to hold the bowel in a condition of rest so as to facilitate the formation of adhesions. As the degree of sepsis increases the pulse becomes more and more rapid and weak and finally a characteristic picture of acute septic peritonitis with the corresponding high temperature, rapid, weak pulse, delirium, dry, coated tongue, obstinate constipation and distention, etc., presents itself. In some of these cases we have a rather more asthenic type with rapid, weak pulse, cold, clammy skin, normal or subnormal temperature. Respiration is increased in frequency and thoracic in character, and may be out of proportion to the temperature and pulse rate. These cases of acute gangrenous appendicitis may, at the outset, on account of the sudden onset and lack of symptoms of previous illnes, readily be confounded with cases of perforation of the stomach, duodenum or gall-bladder, or with ruptured pus tubes. A point which is of much value in differentiating these cases from those of perforation of stomach, intestine, etc., is the marked local tenderness over the region of the appendix. Later, after peritonitis has become well marked, and with the abdomen tense and swollen, it may be more difficult to locate the trouble in the appendix and to differentiate them from cases of perforation of stomach, intestine, etc. In case of doubt an exploratory incision should be made in the linea alba and search made for the seat of the trouble.

Treatment.—Only in the first set of cases, the catarrhal, can there be any question as to the method of treatment—whether to operate as soon as the diagnosis of appendicitis is made or to wait with the hope of the attack subsiding, or to avail oneself of the advantage of an interval operation. If sure of the character of the lesion we may temporize in this set of cases; it will do no harm watching the patient carefully for any sign of danger. Many of them resolve without going on to suppuration or gangrene and therefore escape operation during the acute attack. Some of them, with strict attention to diet, bowels, etc., never have another attack; still this is the exception to the rule. Nature may be assisted in her effort to effect a spontaneous cure in these cases by enjoining complete rest, withholding all food, and permitting only water to be taken, and by the administration of small repeated doses of calomel and bicarbonate of sodium. An icebag may be applied over the region of the appendix. If there is any doubt as to the exact pathological condition existing operation should be advised, except when the presence of some organic disease of the heart, lungs, kidneys, etc., would make an operation extra hazardous. Under these circumstances one might wait with operation until the indications became more imperative. If the patient recovers without operation from the acute attack operation should be urged for the purpose of removing the appendix, unless some distinct contraindication, as mentioned above, is present. Appendicectomy in these simple catarrhal cases and in experienced hands is practically without danger, either immediate or remote, and gives the patient the only certain assurance against subsequent attacks, which are so apt to occur. Sure enough there may never be another attack, but the reverse is the more likely because after one or more acute attacks the appendix is left in a damaged condition that makes it susceptible to renewed attacks. The possibility of being out of the reach of proper surgical help in a subsequent attack is a potent argument in favor of an interval operation. In these cases of simple catarrhal and so-called interval cases amputation of the appendix and inversion of the stump through a gridiron incision in the abdomen is the most satisfactory method of operating. No drainage is necessary, and the abdominal incision is closed layer by layer with catgut.

As to the second group of cases there should be no question concerning the proper method of treatment. Operation should be undertaken as soon as the abscess is diagnosed—abscess means adhesions, and adhesions mean good prognosis. Through an incision corresponding to the location of the tumor, by preference carried between the fibers of the rectus, the abscess is evacuated and the cavity cleansed out with saline poured from a pitcher, followed by peroxide of hydrogen, and this in turn washed away with the saline, and the appendix then sought for and removed. It is desirable to remove the appendix in all these abscess cases. A careful search should be made at the time of operation for a concretion that may have escaped from a perforated appendix into the abscess cavity. Such a concretion is often flushed out with the escaping pus when the abscess is opened or with the saline when the abscess cavity is being flushed out. If a concretion is overlooked and left remaining in the abscess cavity it may keep the wound open for a long time and make the healing process tedious, or it may necessitate reopening the wound to search for and remove the concretion. In most cases after the appendix has been separated it can be amputated close to the root and the stump turned in and the opening

corresponding to the turned-in stump closed with a purse string. In some cases the cecum is so tightly fixed within the abdomen by an unusually short mesocecum that it is almost impossible to draw the cecum sufficiently far out of the abdominal incision to permit of properly applying the purse-string suture about the root of the appendix for the purpose of inverting the stump, and in these cases one may have to be satisfied with applying a ligature of catgut around the root of the appendix and after amputating the organ touching the end of the stump with a drop of carbolic acid on a probe.

These abscess cases should all be drained for 48 hours or longer with a cigarette drain. In some cases where the abscess reaches upward behind the colon toward the kidney it is wise to provide counter-drainage through an additional incision in the loin just above the crest of the ilium—this counter-drainage will not often be found necessary. The incision in the abdomen is closed, except for that part where the drain emerges, layer by layer, with chromic catgut reinforced by several interrupted through-and-through heavy silk sutures.

The question of closing the incision in these cases without drainage.—This may be done in those cases where it is possible to evacuate the abscess and cleanse the cavity thoroughly and invert the stump of the appendix. Some of these will show primary union, still others will break down and on account of there being no ready-formed vent for the pus it undermines the skin and does much more damage than if a drain had been left.

In a series of thirty-five cases treated by the writer without drainage about one-half of them broke down within a few days and had to be opened and drained. In these cases the pus was invariably found between the layers of the abdominal wall—usually in the fatty layer underneath the skin. The peritoneum seemed to be well able to dispose of any infectious elements left behind, but not so the layers that make up the abdominal wall. The discharge of pus when the abscess is opened and the delivery of the diseased appendix through the incision in the abdomen necessarily infect the edges of the incision, and although in some few cases we could get along without drainage still the drainage does no harm and if proved to be not necessary it can be removed after forty-eight hours and really does not delay healing very much if at all.

The third group of cases.—It is of the greatest importance to recognize these cases early and to operate without delay. They are usually first seen by the physician and the responsibility is his to promptly make the diagnosis, to promptly recognize the dangerous nature of the lesion. Early operation will save a very considerable number of these patients who would otherwise be certainly lost. There are no limiting adhesions and delay is fatal. The deadly results are due to failure to recognize these cases—to distinguish them from the ordinary less dangerous varieties. They should be operated upon before the system is overwhelmed by absorption of the septic material. If seen late, after the patient has become thoroughly septic—the system thoroughly saturated with the poison—and the heart has begun to fail, operation will be of no avail. It is simply a question of the degree of poisoning at the time of operation and the individual patient's power of resistance. When the heart is still strong and not rapid the prognosis is good—means either a small degree of absorption or a high degree of resistance. After the poisoning has become more intense and the heart begins to show the effect of the poison by increased frequency and diminished strength of its beat, the prognosis is less favorable. With a pulse rate of over 130 the prognosis is poor, with a still more rapid heart, 140-150, meaning a still greater degree of poisoning—lack of resistance on the part of the patient—the prognosis is bad. It is almost without hope to operate when the heart action indicates that the patient is overwhelmingly poisoned because even after the surgeon has eliminated the source of the infection the system, kidneys, etc., is unable to throw off the poison which has already been absorbed, and the heart rapidly succumbs to the effect of the deadly toxins. However, even in these desperate cases operation should be resorted to as the only measure offering hope. A good free incision is made and the appendix sought and removed. If operating early and the abdomen is free from serum and pus, and we have succeeded in inverting the stump of the appendix, the incision in the abdomen may be closed up without drainage. The peritoneum will itself dispose of septic products if not in too great quantity and if the source of supply is cut off. Even in these cases, however, there can be no harm in leaving a cigarette drain in the end of the incision, reaching down to the site of the turned-in appendix, for forty-eight hours. If operating later and a considerable amount of sero-pus is found in the peritoneal cavity, this should be removed thoroughly by dry sponging and flushing of the immediate neighborhood of the appendix with saline, followed by peroxide, and this, in turn, by saline. The abdomen should be wiped dry and a cigarette drain introduced which reaches down to the former site of the appendix. The purpose of the drain is not to drain the peritoneal cavity, because that is impossible, but just to drain the immediate site of the appendix and the incision. This drain is removed at the end of forty-eight hours and if it does no good it surely does no harm. Elaborate flushing out of the entire abdominal cavity is not, as a rule, necessary in these cases—it is not a limited quantity of septic material which might remain in the peritoneal cavity after operation, but that which is in the lymphatics and blood-vessels and which has already been absorbed before operation is undertaken, that renders the patient's condition desperate. The blood-letting during the operation and the intravenous infusion of saline solution to replace the poison-charged blood are measures that benefit materially in these cases.

104 West Seventy-first Street.

A PSYCHOLOGICAL STUDY OF HAMLET.

By JOHN W. WAINWRIGHT, M.D.,

NEW YORK.

"No one mortal," says Furness, "save Him whose blessed feet were nailed for our advantage to the bitter cross, ever trod this earth commanding such absorbing interest as Hamlet, the mere creation of a poet's brain. No syllable that he whispers, no word let fall by those near him, but is caught and pondered as no words ever have been, except of Holy Writ. Upon no throne built by mortal hands has ever beat so fierce a light as upon this airy fabric reared at Elsinore."

In presenting that phase of Hamlet's character which may be termed the mental, we approach a personality like unto an alabaster lamp, one ever shining forth the light of a noble and exalted soul.

Mysterious as have ever been the motives which

moved Hamlet, there is yet withal, strangely enough, something familiar in the character notwithstanding its seeming obscurity. That he is forever suggestive, but never explicable, is due to our own limitations. He moves through the shadows which divide night from day, passing at times into the rich sunlight of the declining ever, at other times lost in the evening mist of seeming obscurity and the shadows of thick gathering darkness. Sympathy is the one vital part of a comprehension of Hamlet's character. When we can conceive him as a part of our own lives, as we can of other dear friends who are with us no more, as flesh of our flesh, bone of our bone; see him as a personal entity, endeared to us by his frailties as well as his profound religious sentiment, as one of exquisitely tender conscience, deep paternal feeling, of the most exalted ideas of justice; take him into our lives, our hearts, we will in a measure be able to comprehend the motives which moved him. Only by careful study and mature reflection can we hope to understand or appreciate the sublimity of this character.

The opening of the play of Hamlet has almost the effect upon us of viewing the supernatural, to be quickly followed by stern reality. We first see the central figure as he is, pleasing, polished, courteous, with princely dignity. Calm of temper, artless in conduct, albeit meditating upon the sudden death of his beloved father, his mother's disgraceful marriage to his father's brother within one month of her husband's death, thereby depriving him of his rightful crown, to be quickly followed by the revelation of the ghost and his sudden resolution to feign madness, believing at first that his mind is disturbed beyond mortal reach, yet that his power of intellect can and will control this mental disturbance, even render it an instrument for his personal safety. All else must give way to his vow, which is to live "Within the book and volume of my brain unmix'd with baser matter." Ophelia is to be henceforth but a "Trivial fond record" compared with this one purpose of life to which he dedicates himself. All else is to be forgotten. The appeal "Remember me" is not to be for an instant lost to memory. And yet, withal, he cannot see a course clear enough to satisfy his understanding, so,

> "I'll have grounds
> More relative than this: The play's the thing,
> Wherein I'll catch the conscience of the King."

Hamlet believes Ophelia to be in the conspiracy, acting a part at the command of others, spying upon his actions to aid in plucking out the heart of the mystery with which he surrounds himself, in fact hears her assert an untruth. It is then that he rails at her and bids her to a nunnery. After this interview he recovers his tranquillity, for there is great business on hand. He has the interview with the players and here indeed we have preeminently the "scholar's tongue." He becomes calm and addresses Horatio:

> "There is a play to-night before the King;
> One scene of it comes near the circumstance
> Which I have told thee of my father's death.
> I prithee when thou seest that act afoot,
> Even with the very comment of my soul
> Observe my uncle: If his occulted guilt
> Do not itself unkennel in one speech,
> It is a damned ghost that we have seen."

With Ophelia during the play he is both pathetic and humorous. "What should a man do but be merry?" The king is "Frighted with false fire," his occulted guilt has disclosed itself. Hamlet is elated; Rosencrantz and Guildenstern suffer from his biting sarcasm. Polonius is the butt of his wit, but withal

> "Now could I drink hot blood,
> And do such bitter business as the day
> Would quake to look on."

Now follows the scene with the Queen when Hamlet gives the lie to his madness so effectually as to disarm all cabal. Polonius, the wretched, rash, intruding fool, falls instead of his betters. There is no regret on the part of Hamlet. "Take thy fortune," he commands. He must now to England, and he casts himself like a feather upon the great wave of fate. "I see a cherub that sees him." Later he relates to Horatio his device to rid himself of the King's two spies, Rosencrantz and Guildenstern. There is here no lack of resolution for he is *all* will and revels in the telling of the story. He anticipates the issue will be shortly known.

> "It will be short: the interim is mine,
> And a man's life's no more than to say one."

Now follows the scene with the grave diggers. Again he revels and we hear from his lips a veritable mine of wealth. He discourses equally of the most familiar things of life and gives utterance to the sublimest thoughts ever listened to from man, with all the simplicity of which only the scholar is capable.

But again, a frenzy seizes him when he sees his beloved Ophelia laid to rest, and here for the second time his reason totters and comes perilously near forsaking him, but later he becomes again master of self, meditates with Horatio, and becomes almost playful. Still he is at the mercy of fate and again the central figure in the Empire of Chance. The end draws near. Events follow with startling rapidity when guilty and innocent alike perish.

Such in brief is the story of Hamlet.

The student of sociology, in full sympathy with the accepted theories of evolution and the survival of the fittest, believing as he does that human, as well as other affairs, obey irrevocable laws; that life presents an unbroken chain, each link a fact, and the offspring of a preceding fact; that events control men and not men events, will regard the character of Hamlet as an artistic representation of an ever recurring event in the world of facts. To such a one Hamlet cannot escape from his environment for he is but a part of certain well defined phenomena, recurrent in the world, and must necessarily go down in the wreck of a society rotten to the core. That a new and sounder era opens with the advent of Fortinbras matters not, and if known could not have altered his purpose or destiny. Does such a materialistic theory, however, accord with other writings of Shakspere? We find in al of his productions, profound sympathy with the individual a salient point; nor can we conceive him in his maturer years, entirely reversing his previous practice to deal alone with problems, ideas, fragments of political philosophy rather than with a noble and generous soul. We believe that in this as in other of his creations, Hamlet had his being through sympathy for humanity; that Shakspere* did not intend him to

* Malone, in his "Inquiry," published in 1796, confesses that he and Mr. Steevens, in tracing the three signatures affixed to Shakspere's Will, conceived the idea that in the second syllable there was an "a" in one of the signatures, and that notwithstanding the fact that this was clearly shown them later, "it occurred to me (Malone) that in the new facsimile of his name which I gave in 1790, my en-

be a coldly calculating being who exhauts the relations and consequences of a deed or life on "thinking too precisely on the event," still leaving "this thing to do," or as one with enormous intellectual activity lacking wisdom in its use; as one of great powers of reflection, with but a small modicum of sentiment or feeling; as a philosophical being "too subjectively reflective to care in the least for what was occurring in the world around him;" as one whose course of thinking apart from action had destroyed his capacity for belief, since in belief there exists an element contributed by the individual will; as a man in whose mental and moral nature the "finite dislimbs and dissolves," leaving him in the presence of an idea only; as a man so prone to the very cabalism of his intellectual nature, that he meditates upon and plays in the presence of human dust with the base affinities of our bodily nature, which proved so irresistibly attractive to his imagination that he is compelled to pursue the history through all its series of hideous metamorphosis; or as one constantly wavering between materialism and spiritualism, between immortality and disbelief, between reliance upon Providence and a blind bowing to fate. This is not the Hamlet of Shakspere. Hamlet was not so fashioned, not so intended; not cold, cynical, constricted. He was to those who surrounded him as much a mystery, unfathomable, unknown to all but to Horatio, as to us to-day. Even now, looking upon the character after his whole life has been exhibited, there are those who fail to comprehend him or the motives which moved him. How then can it be expected that we follow the subtle meaning of such seemingly inconsequential doings?

We approach the distinguishing and vital element in Hamlet's character: What is this mystery which still baffles the critic? They generally accord him elevated thought, rare sensibility to virtue and vice; an intuitive knowledge of his fellow man; a transcendentally vivid imagination; a highly emotional nature; a glowing exuberance of spirit, which even the most profound sorrow could not wholly suppress; a tender, affable, courteous disposition; a mind graceful and contemplative, full of thought for those around him, but never losing sight of their relations to his own individuality and purpose. One critic writes that he has the common sense of an Englishman, the peculiar incision and mercurial mental force of a Frenchman, the emotional nature of a Celt, the fire and genius of an ancient Greek, the imagination of a modern Italian. Upon whichever side we view him, we find the same beautiful, pathetic light, not a light to illumine a theory or to represent an ever-recurrent phenomenon of evolution, but a light from a noble and exalted soul. Here we have the complex qualities, the thorough assimilating of the noblest attributes of man; the concentrating into one person, of mental characteristics hitherto unknown; a commanding personality, leaving the critic in a bewildering maze of uncertainty as to what manner of man this may be. "Hamlet" has all the paternal and patriotic love of Brutus, the sentiment of Richard II, the bonhomie of Henry V, the will power of Richard III, the statesmanship of Henry IV, the honesty and simplicity of Othello, the loyalty of the better half of Macbeth. In one supreme effort Shakspere has given us a man of amazing powers; lofty conceptions, immaculate faculties, who curiously gazes upon human character and destiny, and then places him in the midst of all that is false, affected, exaggerated, corrupt in human life. The result is of necessity the supreme tragedy of all ages; the very complex of human sufferings.

In such an atmosphere of selfishness, espionage, deceit, he is at war, but battle as heroically as he may, he is unable to adjust his ideal. His environment is too much for him, and he is forced to yield to the utter hopelessness of the task. "The shortness of his allotted span, and the exigencies of life, will not permit man the luxury of overestimating his powers or his responsibilities; he must be content as is the atom, doing its inevitable work in the universe, accept calmly the fate of his nature; cast his follies and his wise acts with equal tranquillity into the great whole, which under the guiding law of destiny, will surely shape them to their proper ends; for let a man be never so wise, he must some time drift at the mercy of fate, without anchorage; and let him be never so foolhardy, fortune will at times bring his boat safely into the harbor of peace. The race is not always to the swift, nor the battle to the strong, nor yet riches to men of understanding, nor yet favor to men of skill; but time and chance happeneth to them all." To Horatio, Hamlet exclaims:

> "There's a divinity that shapes our ends,
> Rough-hew them how we will."

And again to this same faithful friend, whose love was the only foothold on earth left him, he exclaims when rejecting the advice which might have prevented the consummation of a terrible ending:

> "We defy augury; there's a special providence in the fall of a sparrow. If it be now, 'tis not to come; if it be not to come, it will be now; if it be not now, yet it will come: the readiness is all: Since no man has aught of what he leaves, what is't to leave betimes?"

We cannot, we must not, represent Hamlet, who possessed so profound a religious sentiment, exquisitely tender conscience, deep paternal feeling; of the most craving and sensitive nature, coupled with an imagination of such far-reaching power and vastness, as a cold, calculating, rationalistic philosopher who views the world and all around him as would the anatomist.

The motive force in Hamlet's character is his emotional nature. Romeo was steeped in passion, Hamlet saturated with imaginative emotion which compelled him to suffer in an environment utterly false, affected, exaggerated, against the contemplation of which his whole being cries out. The constant exhibition of a realistic rationalism, of cynical philosophy, of an idealism closely approaching pessimism, which at times discloses his inner nature, his very self, is the mask to conceal the internal fires which were consuming him; a part of that "antic disposition" which he thought it necessary to assume, in assuming which, however, he was continually forced to walk as it were, on ice which threatened to give way beneath him at any and the most unfavorable moment. In his solitude we see him "at times all wrath and fire," soliloquizing as it were, from a distant world, a world

graver had made a mistake in placing an "a" over the name, and that what was supposed to be that letter was only a mark of accentuation with a turn occurring in the first part of it, which gave the appearance of a letter. An autograph was found in a small folio volume of the first edition of Florio's translation of Montaigne, purchased at auction in 1838 by the British Museum, in which the Master had written his name "Shakspere." There are numerous warrants for this spelling, but we believe the above will be sufficient to convince any one that the spelling herein used is the proper one.

inaccessible to others, bewailing the fate that compelled him to live in the midst of such meanness, such absolute littleness. Then we see his very soul in active rebellion, and witness his highly wrought nature giving way to fierce bursts of indignation, resentment and revenge; this to be followed by a recoil, and he is dissolved in tears, "weeping to find that he can feel so much and do so little."

The so-called madness of Hamlet was plainly a part of the mask which was to shield and protect him against his enemies and which was voluntarily assumed as is made clear in the first act, when after the interview with the ghost, which almost shook his reason from its throne, and he hears his friends calling him, he answers with the falconer's call, "Come, bird come," and later, after enjoining them to silence he astonishes those who anxiously solicit news of the character of the interview with:

"There's ne'er a villain, dwelling in all Denmark
But he's an arrant knave."

This assumed insanity we think was a mistake, for instead of assisting him in his purpose, it was ever retarding him. It does not appear to have been so much the death of his father as the manner of his going that disturbed Hamlet. He was also much disturbed at the sudden and unwarranted espousal of his uncle by his mother. We can easily believe that Hamlet never had any affection for Claudius; this becomes aversion upon the marriage and positive hatred through the disclosures of the ghost. Nor do we believe that he was much disturbed in the loss of the throne, for he nowhere refers to it. We have rather to deal with a sudden revulsion of feeling, from deep affection for his father to positive hatred for his uncle, and it is this violence to his nature which cries out against his wrongs. Let one whose mind is tuned to the highest and noblest impulses of man; one of such a delicate and refined sense of moral excellence, be cruelly trampled upon and his whole being is in active revolt. This sense of outraged justice becomes more and more accentuated as Hamlet finds himself suspected by the king, who is conscious of having committed a heinous crime in the murder of his brother, and a rank injustice to Hamlet, the rightful owner of the crown of Denmark. He is therefore ever watchful, fearing for his own safety should Hamlet suspect the truth. The knowledge of this suspicion forced Hamlet to cloak the knowledge of the manner of his father's death was incoherent and inconsiderate behavior in order to protect himself. It was the exigencies of his position which influenced his actions and thus is the pitiful cry, "To be, or not to be," which cry pervades the whole tragedy.

Alienists have ever been close students of the character of Hamlet; they would like to place him under restraint and judicial treatment, for they are never sure of their diagnosis; they find it even harder to hit upon a definition of madness than did Polonius:

. . . . "for, to define true madness,
What is't but to be nothing else but mad?"

Tender and nobly descended, this royal flower grew up under the direct influence of majesty, filled with ideas of right and princely dignity, feeling for the good and pure, ever conscious of his high birth and his destiny. "He was a prince, a born prince." Pleasing in figure, polished by nature, courteous from the heart, he was the model of youth, the delight of the world. His:

"The courtier's, soldier's, scholar's, eye, tongue, sword:
The expectancy and rose of the fair state;
The glass of fashion, and the mould of form,
The observ'd of all observers!"

Picture to yourself this youth, this son of princes; conceive him vividly; bring his condition and surroundings before your eyes, and then observe him when he learns that his father's spirit walks; that father whom he idolized and whose untimely taking off but one short month past has caused him such sincere grief. Stand beside him on that terible night when the venerable ghost appears before him. A horrid shudder seizes him! He speaks to the mysterious form; it beckons him to follow and hearken. The fearful accusation of his uncle rings in his ears; the summons to revenge and the piercing reiterated prayer, "Remember me"—that father foully murdered—and his pitiful cry, "Oh, all yon hosts of Heaven." When the ghost has vanished, whom do we see before us? We have heard Hamlet petition the ghost to:

"Haste me to knw't, that I with wings as swift as meditation, or the thoughts of love, may sweep me to my revenge."

But now amazement and sorrow overwhelm this solitary young man; he raves against smiling villains, swears never to forget the departed and concludes with:

"The time is out of joint; O cursed spite!
That ever I was born to set it right!"

Critics have declared Hamlet weak and vaccillating. We do not concede this. On the contrary, we see everywhere evidences of a tremendous will. Was ever resolution more strictly observed than his resolve to abandon every purpose of life in order that he might devote himself solely to his revenge; or his renunciation of his love for the sweet and beautiful Ophelia?

We see this stern resolve again in the killing of Polonious; in his sending his schoolmates, Rosencrantz and Guildenstern, "to sudden death, nor shriving time allowed."

Finally in his firmness to resist the opportunity to kill Claudius while at his prayers. This would never do, for to kill the king when so occupied would be to send him straight to heaven. His father's sufferings rise in his mind, the father whose spirit is:

"Doom'd for a certain time to walk the night;
And for the day, confin'd to fast in fires,
Till the foul crimes, done in my days of nature,
Are burnt and purg'd away."

He contrasts the happier criminal with the purgatory of the victim, and the contemplation fills him with a desire for a fuller revenge. Hence:

"Up, sword; and know thou a more horrid hent: (grasp)
When he is drunk, asleep; or in his rage;
Or in the incestuous pleasures of his bed;
At gaming, swearing; or about some act
That has no relish of salvation in't;
Then trip him, that his heels may kick at heaven;
And that his soul may be as damn'd, and black,
As hell, whereto it goes."

We love Hamlet, the sublimest of Shakspere's creations. There is scarcely a trait of character, of frailty, or grandness that endeared our most beloved friend to us in real life that is not to be found in Hamlet. We love and sympathize with him in his intense sorrow; wish that we could help, could counsel, could put our arm within his and saunter off to some quiet nook where we might talk it all over. We would have patience with him and his ravings at fate, and sympathize, oh, so much, with him in the loss of such a father, for:

"He was a man, take him for all in all,
I shall not look upon his like again."

We love Hamlet, and we love his one friend in all the world, Horatio. Not so much because of his personality, perhaps, but because he was loved by our friend. This one love of Hamlet's to which he indulged himself was his only dependence, the one link that bound him to humanity; "all else was dark and dank."

"Dost thou hear?
Since my dear soul was mistress of my choice,
And could of men distinguish, her election
Hath seal'd thee for herself: for thou hast been
As one, in suffering all, that suffers nothing."

In the tone of Hamlet's words at the close of the first act, there was the formless presentiment of coming misery; and now again, in words which are almost his last:

"But thou would'st not think how ill all's here about my heart," there comes over him the dark foreboding of the final catastrophe. The colossal shadow of his tragical end is projected over the closing scenes of his life, and his being thrills to its gloomy inspiration. As the appointed minister of nature's vengeance for a great crime, he is in most intimate harmony with the rest of nature, and an instinctive feeling, mysterious and inexplicable, forecasts unconsciously that issue by which it is subsequently interpreted. He defies augury from a conviction that his hour must come at the appointed time. With the unfailing certainty of destiny it comes; the "self-sacrifice of life is o'er" and "the rest is sublime." (Silence.)

. . . . "Horatio, I am dead;
Thou liv'st; report me and my cause aright
To the unsatisfied."

Horatio, with breaking heart:

"Never believe it;
I am more an antique Roman than a Dane:
Here's yet some liquor left."

And again Horatio's farewell:

"Good night, sweet prince;
And flights of angels sing thee to thy rest."

We believe that Shakspere loved Hamlet beyond all his other creations. The play everywhere shows the loving master. Like the fond lover, when our Hamlet is present we are satisfied; when absent we long for his return. We love him because he existed; he was and is a part of our lives. But our prince has passed to his eternal heritage; the heritage of immortality; for so long as men shall live, so long must they regard Hamlet a part of their lives. Men will come and go, nations be born and die, but, like the towering mountain and the mighty seas, Hamlet will remain a blessed heritage to man.

In expressing our estimate of this sublime character, let us not too hastily assume a knowledge of the motives which guided him, but rather let us seek to fathom the depths of his understanding; to feel with him; be his counterpart, his ego; realize his environment and his heartaches. Not until we can thus claim acquaintanceship with Hamlet are we warranted in passing judgment upon this, the most human and lovable of the master's creations. When we can know, feel and completely sympathize with him, when we can comprehend the great master and enter with him into the building up of this ever-living personality, then and not until then can we know his purpose or understand his meaning.

"Canst thou bind the sweet influences of the Pleiades, or loose the bonds of Orion? Canst thou bring forth Mazzaroth in his season? Or canst thou guide Arcturus with his sons?"

Then Job answered and saith:

"Behold I am vile; what shall I answer Thee? I will lay mine hand upon my mouth."

Note: To those wishing to pursue this subject further I would suggest a reading of the criticisms by Dr. Maudsley, George Henry Lewis, Dr. Conolly, Hudson, Coleridge, Schlegel, Dowden, Furness, Hazlitt, Victor Hugo, and numerous others, all of whom I have consulted and some of them quoted in this paper.

177 West Eighty-third Street.

CUTANEOUS TUBERCULIN VACCINATION IN THE DIAGNOSIS OF TUBERCULOSIS.

By WILLIAM J. BUTLER, M.D.,

CHICAGO.

ASSISTANT PROFESSOR OF DISEASES OF CHILDREN, RUSH MEDICAL COLLEGE, UNIVERSITY OF CHICAGO; ATTENDING PHYSICIAN, COOK COUNTY HOSPITAL.

It would seem that the hypodermic use of tuberculin as a diagnostic recourse in suspected tuberculosis is destined in the near future to a very limited application, in view of the recent advances made in the diagnosis of tuberculosis. We cannot fail to appreciate the introduction of the opsonic index and the cutaneous tuberculin vaccination as distinct advances in the diagnosis of tuberculosis, when we realize what a powerful agent for harm tuberculin may prove when used hypodermically, for diagnostic purposes. The special training necessary and the elaborate technique incident to ascertaining the opsonic index may, unfortunately, render its general use for the present impractical. On the other hand, the cutaneous tuberculin vaccination commends itself because of its simplicity of application.

The opposition that has grown out of unpleasant experiences with the hypodermic use of tuberculin may cause some hesitation in taking up this new method. And while it is probably too soon to allay all apprehension from its use, in view of a recent report by Moro (*Wiener klinische Wochenschrift*, No. 31, 1907), the cutaneous tuberculin reaction is unattended by any febrile reaction, and possesses the advantage of being applicable also in cases accompanied by elevation of temperature.

In order to follow the development of the cutaneous tuberculin reaction for tuberculosis, it is necessary to revert to a consideration of vaccination against smallpox.

The clinical manifestations of first vaccination are quite familiar. We expect after inoculation with bovine or human lymph a local reaction, consisting of a slight hyperemia against the trauma inflicted in scratching. This usually subsides in less than forty-eight hours, leaving merely the scratch marks, when a period of quiescence supervenes. About the third day, sometimes later, a papule appears at the inoculation site.

This increases in size, the central part being raised and flattened, with a red margin known as the aula. The papule continues to grow and soften in the center, the hyperemia around it spreads, and the aula merges into what is termed the areola, both papule and areola reaching their maximum extent from the ninth to the eleventh day. They now begin to diminish in size, the areola, as it appeared, disappears quite critically, and the pustule slowly undergoes involution.

The relation of papule and areola as to size and time of development may be graphically represented as in Chart 1.

Some elevation of temperature, as indicated on

the chart, and general disturbance precede and accompany the rapid increase of the hyperemia, seldom lasting more than three or four days. In the course of one to three weeks the remnant of the pustule, in the form of a dried crust, falls off, leaving a purple scar of varying size, depending

chiefly on the extent of trauma inflicted at vaccination.

If the individual is revaccinated after a period of several years, he may present all grades of local and general reaction to the vaccine inoculation, from a slight papule, that gradually dries up, unaccompanied by constitutional symptoms, to a form similar to the first vaccination with papule, pustule, and areola formation locally, and more or less severe general manifestations.

A comparison of the time of development and extent of the areola formation well represents the degree of reaction. (See Chart 2.)

One striking feature to be observed is that the reaction occurs more rapidly and all phases are shorter than in the first inoculation. These varying reactions would seem to depend on the degree of immunity existent at the time of revaccination and the concentration of the vaccine. In many, however, the immunity is not at any time complete, even in the first months following vaccination, because in some cases slight reactions occur, the theoretical significance of which lies in the fact that they reach their maximum inside of the first twenty-four hours, without any general disturbance or elevation of temperature. This is called by v. Pirquet the early reaction of revaccination, which stands in striking contrast to the delayed response of the organism to the first vaccination. He believes it to be a specific reaction between the cowpox lymph and an organism already immunized against the same, that it is not produced by bacterial contamination of the lymph, nor by the albumin of the bovine lymph, as the reaction also occurs when fresh human lymph is used. This early reaction is quantitatively dependent on the amount of virus introduced, as can be demonstrated by using various dilutions of lymph, and distinguishes itself thereby from the first vaccination, in which the degree of the reaction is independent of the amount of the infectious material.

This altered reaction of the organism against vaccine, as shown in the early reaction following revaccination, has its analogy in the serum disease. It is a matter of common experience that several days after the injection of antitoxin there appear an eruption and edema of the skin of the patient, which disappear in the course of a few days. If after the subsidence of the skin change, or some weeks later, the patient is again injected with horse serum, the skin edema and erythema will appear within several hours after the injection. This prompt result naturally suggests a greater sensitiveness to the serum.

In order to lead up to the view advanced in explanation of this change in the reaction capacity of the organism, it may be well to recall the precipitin reaction.

If animal A is injected with the serum of animal B, the reaction of A against the injected serum results in the formation of an antibody known as precipitin. The presence of the precipitin in the blood of animal A may be demonstrated in *vitro*, as follows: "If one mixes the blood serum of A with that of B in a test tube a precipitate will occur. If, however, one mixes the blood serum of another animal of the type of A that has not been injected with the blood serum of B no precipitate will occur.

Some observers attribute the short incubation time before the appearance of the clinical manifes-

tations following the second injection of horse serum in man to the preformed precipitin present in the blood coming in contact with the fresh serum upon injection and absorption.

Pirquet contests this idea, interpreting the prompt reaction by a hypersensitiveness of the

organism to a recent infection and not to an immunity as commonly understood; that this altered reaction of the organism, for which he suggests the term "allergie," is not brought about by precipitin in the serum disease but by analogous antibodies, for which he uses the expression "antibodies of the vital reaction;" antibodies that do not circulate in the blood but (as shown in experiments by Rosenau and Anderson) are fixed on the cell.

He does not consider allergie, as might be construed from the horse serum reaction, identical with oversensitiveness, but rather a general term to cover the large complex known as immunity reactions, of which immunity should be made a subheading, being restricted to those processes where the organism has acquired a complete insensitiveness. He therefore believes the term allergie more applicable to express this altered reaction of the organism in revaccination than immunity.

Pfeiffer explains this altered reaction in the case of revaccination by assuming that there are two antibodies formed as a result of the first vaccination, one which destroys one part of the infectious agent of the vaccine; the other an antitoxin which neutralizes the endotoxin set free by the action of the former. The antitoxin disappears from the blood more rapidly than the bacteriolysin; consequently on revaccination, by virtue of the persistence of the bacteriolysin, the endotoxin is set free without meeting sufficient antitoxin, and gives rise to the inflammatory changes of the second vaccination.

The hypotheses of Pirquet have met considerable criticism at the hands of Kraus and others, but these I will not discuss, as in any event it is the general opinion that the altered reaction of the organism is dependent on antibodies formed after the first vaccination, and the rapid and abortive reaction occurring within twenty-four hours after the second vaccination is caused by a coming together immediately of the already existing antibodies and the virus of the vaccine.

That antibodies are produced by the organism subjected to vaccination can be demonstrated *in vitro*, as follows: if the serum of a calf, taken fourteen days after vaccination, is mixed with vaccine lymph in a reagent glass, allowed to stand twenty-four hours, and then centrifugated, and the overlying fluid removed and used to inoculate another calf, the result of inoculation will be negative.

This prompt reaction in revaccination, as already mentioned, is in striking contrast to the first vaccination where the maximum changes are not reached before the eighth to eleventh day because of the slow development of antibodies against the virus of the vaccine. This early reaction may also be obtained by revaccinating a patient who is at the height of his first vaccination with fever, as well as at a later time.

This is transferring from the test tube to the patient that which was long ago demonstarted *in vitro*, namely, that if one brings into contact the bacteria suspected of causing an infection and the blood serum of the patient, a union between bacteria and antibody occurs if the bacteria are the cause of infection, resulting in one instance in bacteriolysis, in another in agglutination, etc. This union in revaccination results in the local reaction of papule and areola formation.

It would seem perfectly logical that a similar altered reaction of the organism might obtain in other bacterial diseases that have resulted in the production of specific antibodies, and that they should give a similar local response on bringing into contact with them, as in cutaneous vaccination, their corresponding virus. In other words this principle might be employed in the diagnosis of all bacterial diseases *in vivo*, as it may be for vaccine: for instance in typhoid fever, tuberculosis, etc. This has proved to be the case in tuberculosis.

Continuing the above line of reasoning with relation to vaccination and revaccination, it may be well to note that the reaction of the organism against infection with tuberculosis, typhoid fever, etc., results in the production of specific antibodies, which, when brought in contact with their corresponding bacteria or extracts of them in skin inoculations cause a similar local reaction as in revaccination. The characteristics of this reaction in tuberculosis will be described below.

The technique for making a cutaneous vaccination with tuberculin is as follows: Make a 25 per cent. solution of old tuberculin in salt solution. A similar dilution is used in which one volume of a 5 per cent. solution of carbolic acid in glycerin is substituted for one of the volumes of salt solution. Place two drops, one of each solution, separated from each other by a space of two inches, on the outside of the arm, which should be prepared as is customary for vaccination. A small lancet, with a dull tip, which is about one-sixteenth of an inch wide and placed vertically in a metal handle, is used to abrade the skin through the vaccine drops by a rotary motion, removing only upper layers of epidermis. The tip is then cleaned, and at a point midway between the vaccination marks a third abrasion is made without any tuberculin being applied, to serve as a control.

If the reaction is positive a papule, varying in size from 5 to 20 mm. in diameter, at first bright red, later becoming a dark red with a slight areola, will appear at either vaccination point, in the first twenty-four hours; occasionally they are delayed to the second twenty-four hours. Sometimes little vesicles with turbid contents, later becoming confluent, appear over the inoculation site. These fade and disappear in course of several days, leaving at times a little pigmentation. In positive cases in which revaccination is practised similar reactions result. In localized tuberculous processes, as of the glands and bone, the reaction is especially marked in contrast to the milder reaction seen in persons who have healed foci. At the control point, and at all three points, in case the reaction is negative, the slight reddening that follows the scarification disappears in twenty-four hours without any further changes.

As a rule there are no constitutional symptoms following its use, and the local changes at the point of inoculation clear up as noted in the course of several days. However, Moro has recently reported five cases in whom complications arose which he was prone to attribute to the tuberculin reaction. In two a rhinitis developed in six to ten days. In three a conjunctivitis phlyctenulosa appeared, in one only for the first time, the others being recurrent. In another an existing conjunctivitis he thought was rendered worse. In one a tuberculide followed at the vaccination point, but had subsided greatly before the patient left the hospital, a month after inoculation.

Since the introduction of this cutaneous tuberculin vaccination, Calmette has devised a unique modification of its application by using the conjunctiva for inoculation instead of the skin. It is

termed the opthalmo-tuberculin reaction. He employs as a vaccine a one per cent. solution in water of the precipitate obtained by adding alcohol to old tuberculin. If this is dropped into the eye of a tuberculous subject, a decided reaction follows in three hours. The caruncle becomes inflamed and covered with a fibrinous exudate. The inferior cul-de-sac becomes injected and in six hours will be found to contain considerable serofibrinous exudate. The reaction attains its maximum point in from six to ten hours and disappears after eighteen hours in children and after from twenty-four to thirty-six hours in adults. The reaction is said to be painless and unaccompanied by constitutional symptoms.

Chantemesse employed this conjunctival inoculation in the diagnosis of typhoid fever, using as vaccine an aqueous solution of a precipitate obtained by adding absolute alcohol to cultures of typhoid bacilli.

The scope of applicability of the reaction in tuberculosis would seem to be in great part restricted to children, as a large number of apparently healthy adults give the reaction. This, however, might be explained on the basis that a large proportion of adults may have obsolete tuberculous foci or latent bacilli somewhere in the body.

As this is solely a diagnostic test, it is quite evident that the most convincing proof of its value will have to come from the autopsy room. I will, therefore, not cite my own experiences with the test, as they have not been so controlled. And although it has been used very widely in the past several months in Austrian and German clinics, the only comparison of the reaction with post-mortem findings so far has come from Pirquet, who reports (*Wiener klinische Wochenschrift*, No. 38, 1907) on one hundred persons in whom the tuberculin vaccination was made and who subsequently came to post-mortem.

Many interesting points have revealed themselves through this study. It has been observed that children with apparently healed tuberculous foci, which were found only incidentally post-mortem, often failed to give the reaction on first vaccination, but responded on later vaccinations. Here is a point not without some clinical significance in the use of tuberculin vaccination. It might suggest as a conservative proposition the employment of this test only in cases in which tuberculosis is the suspected cause of mischief.

Of thirteen cases in which tuberculosis was an incidental finding at autopsy, in six the reaction in the first and in three only in a later examination proved positive. It was negative in four, in three of which it was made in the last ten days of life.

Of thirty-four persons dying from tuberculosis twenty-four were first tested in the last ten days of life. In thirteen of these the reaction failed, in eleven it was positive.

The test would appear to fail frequently in the last ten days of life in cases of fatal tuberculosis, and not infrequently in cases in which tuberculous processes prove an accidental finding.

In one case that gave a positive reaction, the anatomical examination failed to show macroscopic tuberculosis.

Fifty-two cases that gave a negative reaction to the tuberculin test also proved negative as to tuberculosis at autopsy.

The ages of the above varied from a few months to 14 years; 38 were under one year, 30 of whom were free from tuberculosis; of 33 cases over 3 years of age, only 6 were free from tuberculosis; of the 29 between 1 and 4 years, 13 were tuberculous.

It would appear from these results that a positive reaction in a child is undoubtedly diagnostic of tuberculosis; that failure of the reaction is of little antidiagnostic significance in the terminal days of a tuberculous infection; also that its result in cases of obsolete tuberculous foci might prove negative unless the vaccination was repeated.

A parallel observation with its failure in the last days of fatal tuberculosis is its failure in cachectic children. A deviation from the normal is also observed in vaccinating cachectic children against smallpox, in that there is very little or no hyperemia around the papule which develops quite normally, but usually reaches its maximum later and likewise its involution. The revaccination gives much later positive results than usual. This may find explanation in diminished response of the organism to antibody production.

All in all, it would seem to be a valuable and practical diagnostic aid in tuberculosis, possessing advantages over the hypodermic use of tuberculin in children to such an extent as not to require comment. That it has shortcomings, however, is evident from the above statistics, in that it is not absolutely reliable at all stages of the process.

1487 Jackson Boulevard

THE AFTER-CARE OF TUBERCULOSIS WITH REFERENCE TO EMPLOYMENT.*

By H. R. M. LANDIS, M.D.,

PHILADELPHIA, PA.

The machinery now in use in the crusade against tuberculosis in some respects leaves little to be desired, while in others it is woefully inefficient. The agent first directed against tuberculosis and the one that has reached the highest state of development—*i.e.* the sanatorium for the treatment of the disease in its early stages—still falls short of accomplishing its purpose. The arrest of the tuberculous process as manifested by a disappearance of all symptoms and an apparent state of perfect health is not a difficult task, providing the inroads of the disease are not too great. Most sanatoria can show an apparent arrest of the disease, in its early stages, in about 75 per cent. of cases at a time of discharge. One of the characteristics of tuberculosis, however, is the tendency to relapse, and it is this feature of the disease that only too frequently undoes the good results obtained. The old saying that consumption is a disease of the pocket-book still has a good deal of force. To those with means the question of occupation after restoration of health is usually of minor importance. For the working man, however, wage earning capacity is his one asset, and without it he and usually his family become public charges.

In sanatoria the question of employment after leaving the institution is one that has constantly to be faced. In institutions devoted to the working classes, such as the White Haven Sanatorium, this is especially true, for in many cases a return to the former employment is not to be advised; frequently it is the employment itself or the conditions under which it is conducted that has led to the development of the disease. Under such cir-

*Read at the Tuberculosis Exhibition held under the auspices of the Pennsylvania Society for the Prevention of Tuberculosis.

cumstances the individual simply courts a return of the disease if, for instance, he returns to the unhygienic workshop. The great problem at the present time is not so much how to cure people as how to keep them well once they have been restored to health. People with means usually keep in touch with a physician for some time after completing their term in the sanatorium. The poorer class of patients, however, are too frequently lost sight of and little or no effort is made to keep informed as to their condition or manner of living. It is most important to impress on patients who have tuberculosis, no matter how slightly, that they are in constant danger of a relapse unless they exercise the utmost care in living. No time limit can be put on this period of their existence; for most it means attention to health for the remainder of their lives. They should be warned that at least for a time they must have no ambition except to maintain their health and to accept no position that will be incompatible with the preservation of health. The ambition to make large wages has in not a few instances been disastrous. Better far to accept a remuneration that can be earned without impairing the health than to relapse from the effort to excel. It is most important that patients should report to a physician or a dispensary once a month for at least a year after their discharge; after that the interval may be lengthened. In case there is a prolonged rise in the evening temperature, pleurisy, return of or an increase in the cough, blood spitting, or any acute affection of the respiratory tract (colds, sore throat, hoarseness) a physician should be consulted at once. The maintenance of weight is of the greatest importance. Having in mind that there will probably be some loss of weight after leaving the sanatorium patients should be told that the weight ought not to be allowed to fall below a certain point and should be kept well above that point if possible. The scales give such important information that no one who has ever had the disease should neglect being weighed less often than every two weeks. There is little to be feared in making patients unduly apprehensive as to their health. The great trouble is in being able to impress them sufficiently with the fact that their only safeguard is in constant watchfulness. The too prevalent idea at present is that six months at a sanatorium is all that is necessary to effect a cure for all time. The old question uttered with a sinking heart, "Can I be cured?" has been replaced these past few years by, "How long will it be before I am cured?" The truth of the matter is that even for those who are discharged with the disease "arrested" the battle is not half won.

Occupation is the bugbear that constantly confronts both physician and patient. There is nothing more discouraging than to see patients who have been put in a splendid condition of health relapse and become hopelessly diseased solely and entirely because of unsuitable employment. The relation that occupation bears to tuberculosis is so close that it is now a well recognized fact that the crusade against the disease can achieve no great success if physicians alone are left to grapple with it. There must be an earnest cooperation in all walks of life. If the question is of vital importance to the employee it is no less so to the employer. It is obvious that no patient should return to an occupation that had any part in causing the disease. For this reason it should be determined, if possible, in each case whether the infection was obtained because of the employment or whether it was acquired at the home. It is not uncommon for a man to acquire tuberculosis in an infected house even when his occupation is of the most favorable kind.

The question of work for the individuals who have been entirely or partially restored to health is of the utmost importance. At the present time inability to secure employment adapted to their physical needs drives many patients to accept work which can result in but one thing—a relapse. Many lives are sacrificed in this way. Another factor by no means uncommon is the refusal to employ individuals who have or have had tuberculosis. In some instances the constant failure to obtain work leads to a relapse because nourishing food cannot be obtained; in others failure to get employment in their particular line leads people to accept work they are physically unfit to perform.

In coming to a decision as to the work best adapted to the individual the first consideration must be his physical condition. The amount and character of work he is capable of performing without harmful effects should also be determined before he is discharged from treatment. . . . With this idea of hardening patients it has been the custom at the White Haven Sanatorium, since its opening, to put patients to work after the first month. The work is gradually increased so that during the last month's stay at the sanatorium each patient is performing eight hours work daily.

A limited number of patients, with slight damage to the lungs, who are entirely free from symptoms and whose strength has been restored do not offer so many difficulties. The range of occupations which is open to them is comparatively large and as a rule they will remain well providing they exercise reasonable care in regard to their health.

With those who have suffered a good deal of damage to the lung and in whom the disease has made considerable inroads the problem is most difficult. These individuals must devote the greater part of their time to the requirements of their health in order to hold the advantage gained while under treatment. Work of the lightest sort is all they are fit for, if a relapse is to be avoided. A few hours a day, at the most, is all many of them can stand. I think that most of us are too prone loosely to advise patients, especially if they have been inside workers, to get employment in the open air. A little reflection will show, however, that this is not always sound advise. Employment in the open air is not always easy to obtain for one thing, and is too often of the sort that requires severe muscular exertion when it is obtainable. The great essential for the discharged consumptive is avoidance of fatigue. His occupation should be one that will be free from incessant hurry and great muscular effort. For this reason inside employment is in many instances better than outside work providing the mental and physical tax is not too great and the working place is well ventilated.

To obtain suitable work for "arrested" cases and prevent their returning to occupations prejudicial to their health various expedients have been tried but so far without much success. At present the establishing of convalescent farms and industrial settlements in connection with the sanatoria are being urgently advocated. The object of these farms and settlements is to prolong the stay of patients in favorable surroundings and at the same time teach them some trade or other means of making a livelihood. Industrial settlements in

which suitable trades can be taught offer great possibilities and should receive every encouragement. While convalescent farms are greatly to be desired they require a considerable outlay of money, and in the end, so far as the working classes are concerned, would probably leave us in much the same position that we are at present.

The great need at the present time is for some organization which shall have as its object the securing of suitable employment for patients discharged from sanatoria and dispensaries. The applicant should present at such a bureau a certificate indicating his present condition and the amount and character of work he is capable of performing. To insure the opening of positions for those of limited working capacity it should also be the business of these bureaus to secure the cooperation of employers and others interested in the working class consumptive. The Kelling Open-air Sanatorium in England has found that the question of occupation after leaving the institution is the true solution of obtaining permanency of results in the working classes. With this object in view an After-care Committee has been appointed, the function of which is to consider the future of each patient and to obtain for him employment suited to his physical requirements. A circular letter has been sent to all those interested in employing labor with the request that they keep the institution in mind when they have open a position requiring light labor. Such positions may be filled temporarily until the patient is sufficiently hardened to undertake more arduous labor or they may become permanent, enabling the crippled wage-earner to gain a moderate competence. The employer is in no way to be responsible for the health of the individual. The work solicited is that which may be done out of doors or in pure air indoors and should not be of a character requiring great muscular effort or constant hurry. It is furthermore pointed out, and this is most important, that the employment of such individuals is in no way a menace to others. A man well trained in the proper precautions against spreading the disease is not dangerous to those about him. Realizing the importance of the subject the Pennsylvania Society for the Prevention of Tuberculosis has already organized a bureau on the lines just indicated and proposes to make every effort to enlist the aid of all who are in any way interested in the matter.

One of the most successful and practical methods of treating tuberculosis in the home is that known as the Tuberculosis Class, first put into operation by Dr. Joseph Pratt of Boston. Mention is made of this method because its most important feature is the close relationship between the physician and the patient. Inasmuch as these classes are limited in membership the physician in charge is enabled to become thoroughly familiar with every particular relating to the patient. If the present employment is undesirable, either because it is too arduous or unhygienic the church supporting a class can be enlisted in the endeavor to provide suitable employment for arrested or partially arrested cases. The establishing of more of these tuberculosis classes is greatly to be desired, for aside from the good they accomplish in education and restoring the patient to health they will aid greatly in helping to solve the problem of after-employment. In attempting the selection of an occupation the field is necessarily restricted except in the case of those who have suffered very slight pulmonary damage. Vigorously pushing the campaign against unhygienic working places will eventually be of great help as there are at present occupations with an evil reputation, largely because of the conditions under which they are carried on.

For men of limited working capacity the following occupations may be cited: gardening, light farm work, collecting rents, soliciting insurance, light carpenter work, watchman, gate-keeper, clerical work under favorable conditions, and driving, provided the latter is not associated with loading and unloading heavy articles.

For women the range of choice is not so great, but fortunately the question of employment is not so pressing as it is for men. Suitable employments for women are: mending, sewing, fine needle work, poultry raising, cultivation of flowers, and clerical work. Within the past few years an excellent opportunity for women has been made available by taking up the vocation of nursing, with special reference to the care of consumptive patients. Necessity compelled the Phipps Institute, some three years ago, to establish its own training school for nurses. So far the candidates, and it has been the desire that this should be so, have all been women who have recovered from tuberculosis. This training school is no longer an experiment. Of the twenty odd graduates, all of them are to-day in good health and occupying lucrative positions. Up to date the demand for these graduates to take charge of sanatoria and dispensaries in other parts of the country is in excess of the supply. The success of this plan has led to the establishing of a similar training school at the White Haven Sanatorium.

Enough has been said to show the present neglect of this most important subject and it is to be hoped that in the future that the various organizations dealing with the tuberculosis problem will give to it the attention it deserves.

TREATMENT OF CANCER.

By A. G. HENRY, M.D.,
CORTLAND, N. Y.

If I had nothing different to offer in the treatment of this disease than the usual ones by knife, plaster or hypodermic injections, this article would not have been written. In the too frequent return, either at the site of operation or elsewhere, the results from the use of knife or plaster are very disappointing. For reasons which will be stated further along, I think the treatment by injections will prove about as unsatisfactory. The remark of an eminent physician that everyone would die of cancer if he lived long enough, points to what seems to be the true cause of this disease, and indicates the line along which a rational treatment may be attempted.

The germ theory of this disease we may dismiss as being irrational and pretty thoroughly discredited. But that it is due to faulty nutrition, assimilation, and absorption we may fairly assume, and these conditions are brought about by one or more of a variety of causes.

As regards nutrition, we recognize three ways which make for a departure from health—over-nutrition, under-nutrition and faulty nutrition. By this last is meant that while there may not be too much or too little food taken, the material composing it is deleterious.

In the first case, that of over-nutrition, too much food is taken, more than the body needs for its prop-

er maintenance. As time goes on and this condition of things continues, the blood-making organs become tired and manufacture less perfect material from which the "builders" at some one or more selected places begin to replace with imperfect or cancer cells the more normal tissues of the affected parts. As the eliminative absorbents fail to remove this imperfect material as fast as it is deposited, we have the growing tumor.

Though less frequently, much the same conditions obtain in under-nutrition. The blood-making organs themselves are poorly nourished and furnish poor material for the building of perfectly healthy cells.

By material which gives a faulty nutrition, we have especially in mind all flesh foods which, containing toxins and poisons of various kinds, as so well shown by Haig, Kellogg, and others, are totally unfit for human consumption and have much to do either directly or indirectly in bringing about a condition of things that goes to the building of cancers.

If cancer is a local disease, it should not return after removal, as it usually does. On the theory that there is a general wrong condition of the blood-making assimilative and eliminative functions, it is readily explainable; for usually nothing is effectively done after an operation for the removal of the growth to remedy the wrongs above mentioned; and not only that, but the patient's strength is seriously sapped by the operation itself, if that operation has been accomplished by knife or plaster. Thus an early recurrence is to be looked for. The treatment by injection promises to be but little, if any, more effectual against a recurrence than the operations before mentioned, barring the less severe shock to the system from the little destruction of tissue attending it.

In the aged and feeble, where vitality is low and on the wane, or even in younger persons, where the diseased condition has been allowed to progress so long as thoroughly to saturate the system, we can hardly expect any treatment to avail. But excepting these cases, I think there is a line of treatment which, if most thoroughly carried out, will completely cure a large proportion of those afflicted with external cancers, and that without any surgical operation whatever.

A summary of this treatment was published in the Medical Record of June 6, 1903, in reporting a case referred to me in August, 1900, and to this any interested may refer.

This was a case in which the clinical symptoms of cancer of the breast were complete, a hard, nodular, rapidly growing tumor with enlarged axillary glands, in a woman of the right age for malignant growths (47), with a history of no previous trouble of any kind in the breasts. It had been diagnosed as cancer by competent surgeons and the immediate and entire removal of breast and glands earnestly enjoined. Yet, at the expiration of nine weeks of treatment this woman left for her home in Ontario, Canada, with the tumor entirely removed by absorption and her health in the best condition. There has been no recurrence of the growth after seven years.

To those who prefer to consider that the growth under consideration was probably not malignant, I would respectfully point out that it was a sure enough cancer for the recommendation of an operation of the most radical kind, an operation that would have mutilated and badly crippled for life and tortured in mind as well as in body the victim of such unnecessary assault. To those who saw the growth there was no doubt as to its nature.

This lady, from impaired digestion and poor appetite, together with faulty food, was suffering from under-nutrition, and the treatment of general massage and electricity was used with the object and result of most quickly remedying this condition of things. Now with the overfed, especially if attended by obesity or digestive troubles, the best returns will be realized by a complete fast for a few days, possibly a week or more. This will best give the eliminative absorbents time to catch up with their work, and give the organs of nutrition generally a rest from long overwork. Then shortly they will be in much better condition to further the task of building healthy, perfect cells into the body from pure and sufficient foods, and removing the old, badly formed, diseased ones.

As to cancer of the breast, far-advanced, and when the tumor is large and has nearly if not quite reached the suppurative stage, the course promising the most hopeful results is to excise the diseased mass with as little destruction of surrounding tissue as possible, with no attention paid to enlarged neighboring glands. Better to leave a little of the diseased structure than to make a gap in the tissues that cannot be easily closed with little stretching of the parts. The patient after such an operation can be put upon an appropriate diet at once, and in a few days treatment by electricity and massage for the absorption of the swollen glands and remains of the tumor may be begun.

For internal cancers the general treatment before alluded to, with special diet, etc., offers the most hope succeeding an operation for the removal of the diseased structure when possible.

To recapitulate: Cancer of the breast, when not too large and near the suppurative stage, can be treated with the greatest promise of success with electricity and massage both local and general, together with a special diet from which all flesh foods are entirely excluded. The patient should always be under the physician's immediate care, at his residence or private sanatorium, where every detail of the treatment can be most thoroughly carried out.

"In the special work of dispersing mammary tumors, good judgment and considerable experience give the best results. As delicate a touch and as finely graduated pressure are necessary to success in working about a growth we wish to get rid of as in manipulating pelvic adhesions and enlargements. Unskillful treatment is worse than no treatment."

Finally, and to note that others are thinking of the great importance that diet may have in the production of cancer, I will give a few sentences from a recent address of Dr. Robert Bell of London before the Psycho-Therapeutic Society. He said that self-indulgence was one of the chief factors in the production of cancer; that one of the primary causes was the ingestion of too much red butcher's meat, and that in his long experience he had met only one cancer patient who was a vegetarian and she was sick from other causes.

Fowler's Position.—MacLaren says that this is an important aid in the treatment of cases of general peritonitis. It consists in placing the patient in a semi-erect posture at an agle of 45 degrees or less and maintaining him there by means of supports and pillows. By this means, in septic abdominal cases, the septic fluids from the absorbent and dangerous area of the diaphragm and upper abdomen are drained to the less absorbent and safer area of the pelvis and allowed to escape by a large suprapubic drain which passes to the bottom of the pelvis.—*British Medical Journal.*

THE TEACHING OF PHYSICAL DIAGNOSIS.

By O. L. MULOT, M.D.,

BROOKLYN, NEW YORK.

ASSISTANT ATTENDING IN GENERAL MEDICINE, AT THE UNIVERSITY AND BELLEVUE MEDICAL COLLEGE DISPENSARY.

WERE we to start a discussion of the relative importance of the various subjects of the medical curriculum and the time to be devoted to the study of each, we would have buzz about our ears such a swarm of divergent opinions as to be truly startling. Although there can be little doubt that in the efforts to improve medical education, as in all other reforms, overenthusiasm carried the day and the student now spends much time acquiring that which in many cases is forgotten before he gets his diploma and much that is of little real value in the practical every-day work of nine-tenths of the profession, yet about physical diagnosis there is no such great difference of opinion, and it was an improvement in the teaching of this subject that I had in mind in a previous article.*

About four years ago, in conversation with the head of one of the medical schools of this city, I suggested that diagnosis should be the subject of a special teacher. He dissented on the ground that it was too intimately connected with Practice of Medicine to make such a separation possible and practical. I was not then, nor am I now, converted. The teaching of this subject has always been lax; it is a large subject and when its teaching is incumbent upon the chair of practice the instruction in diagnosis or practice, or both, must suffer. The separation of these two subjects seems much more practical and reasonable than the separation of Materia Medica and Therapeutics into separate branches. A perusal of the announcements of medical colleges shows that his opinion is not universally shared, as some have made this whole subject of diagnosis a separate professorship, and my observation of the theoretical unpreparedness of students beginning their third year's studies has convinced me of the desirability that these men should, during their second year, receive thorough instruction on the basis theory and physics of the subject.

The students realize how defectively and inadequately they have been prepared during the second year and frequently express themselves to the effect that the time devoted to this subject was wasted. I concur in this opinion. True, students do not realize their own needs, but they do form their own estimates of teachers and teaching; they know the weak as well as strong points of each one and there is a singular unanimity of their judgment of teachers. He who teaches in a simple, concise manner, easy of comprehension, has their high esteem.

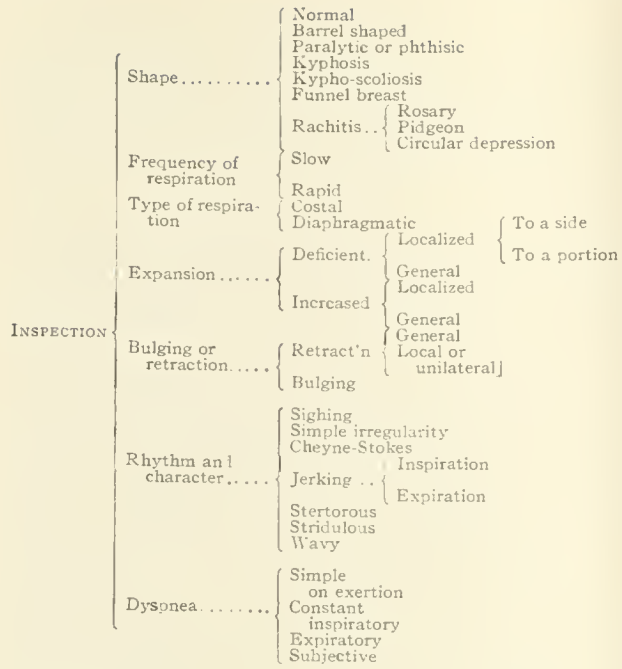
This failure of the second year's teaching necessitates going all over the theory, which of course, under the circumstances, can be done only in the briefest possible manner and at the expense of time that, according to the plan of instruction, was intended to be devoted entirely to practical work. At best the time is short. There is now some talk about making the course in medicine five years. Such an increase would be profitable to the schools, but would work a hardship on the students. The yearly work can well begin a few weeks sooner and continue a few weeks longer, easily increasing its length by six weeks or more. This may seem but a small gain when considered with the single term, but on the whole course it will amount to more than half a term, as it gives an increase of twenty-four weeks or more. I think, in justice to the students, this should be done before another term and its fees are added; but this is wide of my subject.

Nearly every writer and teacher has felt justified in inventing new qualifying terms suited to express his own conception of signs; this has led to a very confusing nomenclature. The very multiplicity of terms tends more to obscure than to elucidate the subject. A Basel convention would certainly not be out of place. In a course of instruction on this subject these terms can be made plain and physical signs explained on the basis of the physical changes which underlie their variations; nor do I mean by this giving students a stated number of pages from the recommended text-book or a subject to be studied from the book and at the next lesson quizzing them upon that. This smacks too much of the "cram quizzes" so much in vogue fifteen or twenty years ago. It may be an excellent aid to memory, but it certainly is not teaching and does not merit so dignified a term. Teaching is something that appeals to the thinking and reasoning powers, while the other is a cramming of the memory and never of enduring good, and a thing which all earnest educators have abandoned because of the poor results thus obtained.

Teachers and text-books speak of the physical signs and recite the diseases in which the changes are encountered. Now we know that the changes in physical signs are dependent upon the extent, nature, and seat of the pathological changes. The student gets a long drill in the pathological laboratory with the microscope, but these microscopic changes must be of macroscopic extent, to cause differences in the physical signs. The gross pathology as seen in the autopsy room at this stage of his studies would be invaluable to the student.

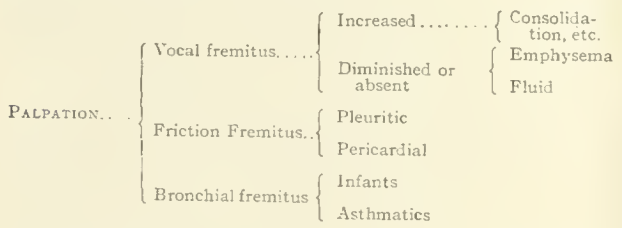
Let us pass quickly over that part of our subject bearing upon the history, its importance, and method of taking and proceed to inspection, and here let the teacher only dwell upon the salient points of general inspection. This in itself is a large subject, but should be dealt with according to the grade and limitations of the student; to give enough, not too much nor too little, the teacher ever bearing in mind that he is building for them a skeleton which is later to be filled in and built upon by the student. This framework must be a simple, still adequate structure. Thus we progress to the special inspection of the chest. Now if we will only for a moment contemplate the structure of the lung we will at once realize that gross pathological changes, recognizable by physical signs, must be along one of two directions: Infiltration and consolidation for one, or rarification for the other, and this fact should be strongly pointed out to the student. These two processes are characterized by changes recognizable in each of the subsequent steps and each gives a group distinctive and diametrical to the other. I need not here go into the evidence of changes along these two lines as discoverable by inspection. Of course, there are many other things discoverable by inspection, but these should be made to stand out as cardinal. If the course is to be clinical as well as didactic and the students are to practise physical diagnosis, a synopsis of inspection such as the following may be given them:

*MEDICAL RECORD, August 17, 1907.

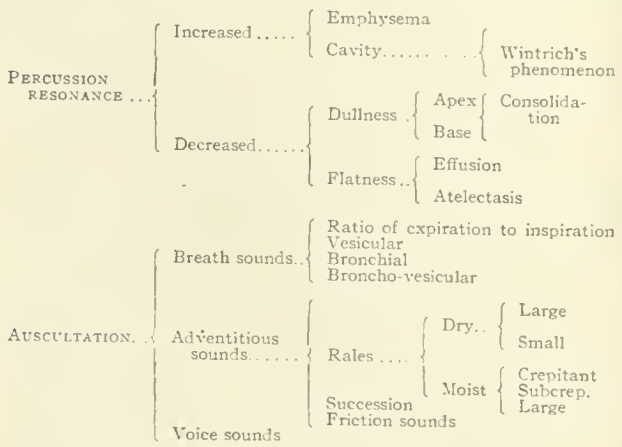


This synopsis can be very much amplified or abridged. I have found it practical and much appreciated by the students, not as an aid to the memory, but as a guide to the order in which to take them up, so as to guard against oversight and to train him in method, system, and sequence, which is also one of the duties and responsibilities of the teacher.

Then, taking up the next step, palpation, work that over, always holding the two processes strongly in view, and when this step is completed the synopsis of palpation may follow:



So on through the succeeding steps, percussion and its synopsis:



If the teaching has been intelligent and consistent, each step thoroughly worked over, even if only in the abridged form as necessitated by the conditions of which I spoke in the earlier part of this article, the student will find little difficulty in recognizing conditions such as pleural effusions, consolidations, etc., for he has learned to look for changes in groups and does not rely upon this or that one physical sign.

"Ah! but there are so many exceptions to this. We do not often have things so clearly cut," is the argument that will be advanced. True indeed, but we have only been building a framework and it is an old-established pedagogic practise to teach first the rule and then the exception, and in this subject I can see nothing better than to follow this time-honored method which has been found to be productive of the best results. Any other method will produce chaos, out of which the student must painfully and laboriously grope his way at the expense of much time and the chagrin of many mistakes. It is so hard to unlearn and to correct bad habits. To avoid this chaos, to save time and drill him in the routine of making examinations, for this he has a teacher. Most of the gross errors in diagnosis are not so much due to ignorance as to incomplete, systemless examinations.

Let us teach physical diagnostics upon the pathology which is responsible for the changes, for after all that is all they tell us, leaving us in ignorance as to the etiology of these changes. The physical signs of a tubercular consolidation are no different than those of a pneumonic one; you may argue that they differ in their location and area involved, but we can and do have tubercular processes at the base, and on the other hand we can and do have pneumonic areas no larger in size than those of the tubercular processes and occupying a location other than the base. Our diagnosis would depend upon the history and symptoms, and I repeat, our physical signs remain simply those of consolidation. In basing our teaching on pathology we are only building upon its own true foundation and making the subject logical and much easier of comprehension, thus placing the student in a position to use his reasoning power, and he should be able to reason out the physical signs from the pathology and *vice versa*.

The study of the diagnostics of the heart is upon a better foundation, but students must be warned against the conception that the various murmurs are pathological entities. This misconception is a common one and easily understood when we look over the dispensary record books. In closing let me lay stress upon the fact that, besides a knowledge and understanding of the subject, the student must acquire a technique; a technique of the eye, the ear, and the hand. It is, therefore, useless to let the beginner listen to murmurs only faintly audible and of doubtful character. The large dispensaries connected with the schools furnish abundance of material of the grosser kind, and as he acquires acuteness of ear let him be brought to the realization of those fainter ones. This matter of technique and its proper development is of no small importance. Musicians devote so much time and care to technique; how much more important is it that this part of the physician's education should be the very best obtainable under the conditions?

619 HALSEY STREET.

Endometritis.—Keep the patient at rest; this is most effectively attained by ordering her to bed. Keep the vagina clean and lessen inflammation in it by antiseptic and sedative or astringent douches; a saturated solution of boric acid if the vagina be sore or the discharge irritating; chloride of zinc (¼ to ½ grain to the ounce) if the discharge is copious. Under such treatment most cases get well in a week or two.—*Herman.*

CONGENITAL IRIDEREMIA WITH CATARACT.

By EDGAR S. THOMSON, M.D.,

NEW YORK.

Congenital irideremia is rather an unusual condition, although a number of cases have been reported. It is almost invariably bilateral and is accompanied by other abnormalities. There is usually a small rudimentary portion of the iris present, and it is doubtful if there is such a condition as complete aniridia. Opacities of the lens are perhaps the most common complications, though the cornea is usually not normal. The vision is usually extremely defective.

The present patient, a man of 36, of good general health, though not particularly robust, came to me January 27, 1901. His vision had never been more than 5/200 to 6/200, as far as could be ascertained. For four years his vision had been failing, and cataract had been developing. Two years previously a needling had been attempted on the left eye, by a local oculist, but the operation had been followed by such severe reaction that no further attempt had been made to remove the cataract. Both lenses, at the time of his first visit, were opaque in all parts but with old stellar opacities more marked at the anterior pole. Vision was P. L. There being no contraindications in his general health, extraction of the cataract in the right eye was advised, which was performed at the hospital two days later. A section was made at the limbus, and capsulotomy was attempted, but the capsule proved to be so thick and tough that it was impossible to cut it, and the lens became slightly dislocated during the attempt. It was thereupon removed with a wire loop, only a drop of fluid vitreous being lost in the maneuver. There was very slight reaction following the operation, indeed the wound remained open until the fifth day, and the vitreous became filled with exudation, so that atrophy of the globe seemed imminent. The patient was kept in bed and mercurial inunctions were used.

On the eleventh day the vitreous began to clear, the slight injection of the eyeball to subside, and the vision to improve. He left the hospital February 23. At that time a good view of the fundus could be obtained; there were no lesions of the retina, choroid, or nerve to be seen; the tension was slightly fuller than in the other eye. Pilocarpin drops were prescribed for him, and he was given a + 10 for the distance, with which his vision was 4/200, and a + 35 for near, with which he read Jaeger type No. 7 by holding it very close to his eye. He returned to his home in Vermont and came back December 3, 1902, with slightly increased tension in that eye, and a dense membrane stretching across the pupil. Under cocaine a De Wecker operation of division of the membrane was done, from which he recovered without incident.

March 4, 1903, the vision was 8/200, the tension normal.

March 2, 1904, he returned with plus tension, reduced vision, and pain in the eye, which he said had lasted about ten days. The field was concentrically contracted to about 20 degrees and there was a deep total cupping of the optic nerve. The vision was reduced to 6/200. He was given a prescription for bichloride of mercury and pilocarpine, and hot water locally. Extraction of the left cataract was advised but refused.

January 2, 1907, he again returned to the city. The left lens had become spontaneously dislocated, and was floating around in the anterior part of the vitreous, moored to its position by a small section of the suspensory ligament. There was slight redness of the eye and immediate extraction was advised. This was done at the hospital under cocaine anesthesia. A section was made well forward in the limbus, and the lens delivered without difficulty by a wire loop. A few drops of fluid vitreous were obtained. As it seemed important to secure immediate healing of the wound, on account of the experience with the other eye, a conjunctival flap was made and drawn over the wound by a suture. The outlines of this flap had been made before the performance of the section, and it only remained to enlarge it and suture it. However, on account of the fact that the sclera was less than half of its normal thickness, it was not found possible to use the flap, as no matter how gently it was drawn over, or how little the tension, the lips of the wound in the limbus would override, preventing perfect apposition. All attempts to suture the flap were therefore given up and it was merely agglutinated as well as possible over the wound. The eye healed kindly, at once, and in two weeks the patient left the hospital with a vision of 12/200 with a + 10.

So far he has done well, but the ultimate course of the case is very doubtful, as the scleral tissues have poor resistance, and secondary glaucoma is very apt to occur.

19 East Forty-fourth Street.

The Tragedy of Tuberculosis.—J. Macdonald refers to the family of a crofter who had lived in the same house for 26 years. Until the spring of 1900 the whole family, consisting of himself, his wife, five daughters, and seven sons, the oldest being 21 years and the youngest 2, had always been healthy. In April, 1906, the eldest girl, aged 21, who had been in service, came home suffering from a suppurating finger. Symptoms of phthisis manifested themselves, and she died of tuberculous meningitis on May 26. In the following November another daughter, aged 14, was found to be suffering from well-marked phthisis in both lungs. Death took place on January 8, 1907. During the time that she was ill the father began to suffer from a cough, and the mother complained of pain in the abdomen and the left ankle. Two daughters, aged respectively 20 and 10, also complained of cough, and the baby, aged 2, was anemic and emaciated, also had a cough. Examination showed that the mother was suffering from tuberculous disease of the ankle and there seemed to be reason to suspect the existence of similar disease in the abdomen; while the two daughters and the baby showed distinct signs of pulmonary phthisis. The baby died on January 3, and the daughter, aged 10, on January 10, after an illness of about three weeks. The mother was removed to the Western Infirmary, Glasgow. The father who up to this point was the only one of the male side of the house to be attacked, did not improve. In March, however, it was found that a boy, aged 15, was suffering from phthisis. Meanwhile the father got worse and died soon afterwards. Attention is drawn to the following points of interest in connection with the outbreak: (*a*) The entire absence of a family history, or predisposition on either side; (*b*) the fact that for twenty-one years the family had occupied the same croft healthily; (*c*) the fact that the disease attacked the female side of the house first; (*d*) the acute onset of the disease in the majority of the cases; (*e*) the rapid destruction of lung tissue, very high temperatures in some, and the fact that there was very little expectoration in any of the cases; (*f*) within three months, father, mother, four sisters, and a brother have all been attacked, with 4 deaths out of 7 cases. The house was of the ordinary type of crofter's dwelling, consisting of two apartments, with stone walls, thatched roof, clay floors, and very damp. The people were particularly clean and tidy, and kept their house in an excellent condition. According to recent information, the mother had died of tuberculous peritonitis in Glasgow. The ravages of the disease have not ended there, and the family is in danger of utter extermination. Its doom recalls the fatefulness of a Greek tragedy.—*British Medical Journal.*

New York, February 1, 1908.

OPERATIVE TREATMENT OF AUTOINTOXICATION.

Metchnikoff has long held the view that the large intestine is man's greatest internal enemy and that it is in consequence of the fermentation processes there going on that so many of us fail to reach the appointed term of life, being cut off prematurely at three score and ten or even earlier. It is undoubtedly true that autointoxication not only causes many discomforts and serious ills, both physical and mental, but may even shorten life, but our knowledge of this condition and of its mode of production is not yet sufficiently advanced to warrant the belief that the removal of the large intestine is necessary to its prevention or cure.

That we may come to this, however, before many years have passed seems within the possibilities. Especially is this so in view of an important contribution to the subject made by Mr. W. Arbuthnot Lane in the *British Medical Journal* of January 18. In this article he reports briefly thirty-nine cases of excision of the large intestine, in whole or in part, undertaken primarily for the relief of intractable constipation. The earlier operations were performed for the relief of the pain attendant upon this condition, but the immediate and startling amelioration, not only of the pain but also of the other symptoms of autointoxication, was so marked that he was induced to operate in other cases of obstinate constipation in which pain was not a prominent feature. As his experience widened, he was led to conclude that intestinal stasis had a very far-reaching pathology, due partly to mechanical causes and partly to autotoxemia; and he then began to operate earlier, before the long continuance of the condition had reduced the sufferers to such a state that the operation, itself one of only "moderate severity," directly jeopardized life. An early operation he found was not only attended with less fatality, but was also more successful in affording complete relief of the symptoms—this being in accord with the fact that the long continuance of morbid symptoms induces a habit, founded doubtless on anatomical changes, which persists after the primary cause is removed. In his earlier operations Mr. Lane removed the large intestine only to the splenic flexure, on the assumption that the descending colon and sigmoid, being vertical, would not afford opportunity for the accumulation of fecal material. This, he learned, was a mistake, and in several instances he was forced to perform a second operation to remove these offending structures. In his later cases he excised the entire large bowel, leaving only the rectum. The most distressing after-symptom was constant and prolonged vomiting which, however, was relieved by copious subcutaneous infusions of saline solution. Another advantage of these saline injections was the prevention of fixation of the dilated small intestine by adhesions—at least they appeared to obviate this complication.

The results of the operation were striking. The relief of the pain and of the autotoxemic symptoms was so pronounced and so immediate that there could be no doubt it was due to the exclusion of the large intestine, thereby seeming to confirm Metchnikoff's theory that the larger bowel is simply an immense incubator for the cultivation of noxious bacteria. The operative mortality was not large—6 deaths among the 39 patients operated upon, or about 17 per cent.—and it is fair to assume that a more careful selection of suitable cases and greater experience may reduce the proportion. Nevertheless it was sufficiently great to raise doubts as to the justifiability of the procedure in any but the most desperate cases. The medical treatment of autointoxication is only in its infancy, and until the condition is better understood, until we have acquired a more positive knowledge of the factors in its causation, and especially until we are sure that the large intestine is really as useless and as harmful as it is accused of being, such a radical measure as the entire removal of this portion of the gut is hardly to be recommended. Metchnikoff claims to have succeeded in restraining the pernicious activity of the intestinal flora by implanting cultures of lactic acid bacteria, and there are other means, dietetic and medicinal, at our command whereby colonic fermentation can be restrained. Until these have been exhausted most of us will doubtless prefer to worry along with our six-foot long sewer. What effect the removal of the colon will have upon the longevity of Mr. Lane's patients must be left to the observation of future generations of practitioners.

INFANT MORTALITY AND INSANITATION.

In all centers of population in the civilized world, the death-rate of young infants is very high. American cities are no exception to this phase of modern life, although perhaps on the whole they are in a better position in this respect than are the majority of European manufacturing towns. The big industrial parts of Great Britain hold a very unenviable place, so far as infant mortality is concerned, and various theories are being continually projected to account for this unsatisfactory state of affairs. Recently some well-known medical men have stated it as their opinion that insanitation has little to do with infant mortality. Of course, the belief of the majority of medical authorities is in quite an opposite direction, and it has been often said that the infantile mortality rate of a district is the index of the sanitary state of that district.

There are certainly some diseases to which very young children are peculiarly liable which cannot be truthfully put down to the sanitary condition of a neighborhood, but with the large group of diarrheal diseases it might be expected that a fairly unanimous consensus of opinion would exist.

However such is not the case. For instance, Dr. Ralph Vincent, in giving evidence before the British Inter-departmental Committee on Physical Deterioration, says: "The great factor in the causes of disease among infants is, invariably, improper feeding. Diarrhea, cholera infantum, atrophy, gastro-enteritis, diseases of stomach, are the chief headings. Inflammation of the bowels, inflammation of the stomach, dentition, bronchitis, pneumonia, and convulsions are generally the secondary results of bad infant feeding."

Dr. Alfred Hill, of Birmingham, another English physician who has made a special study of the causes leading to infantile mortality, has come to similar conclusions. Again the figures given by Dr. Nixen for the Jewish population of Cheetham, in which it is shown that the infantile death-rate among them is much less than that of their Christian neighbors, and the well known fact that although poor town Jews everywhere are massed together under unsanitary conditions, and that the death-rate of their young children is relatively small, seems to be another strong argument in favor of the contention that unsanitary surroundings have no important influence upon the infantile mortality. At any rate, it is certain that a considerable amount of doubt exists even now, as to the significance of the role played by dirt and its concomitants in the causation of sickness and death among infants.

In the *British Journal of the Royal Institute of Public Health*, for January of this year, Dr. E. H. Snell, Medical Officer of Health for Coventry, in a well written article attempts to controvert assertions of this nature. He is of the opinion that the real solution of the problem of how successfully to combat diarrhea, the most fertile cause of infantile mortality, is to aim at two matters: (1) The reduction to its smallest limits of the number of those infants who have to be artificially fed. (2) The provision for those who have to be so fed of a bacteria free food. The author points out that the second desideratum resolves itself into the combating of those factors which tend towards an impure milk supply. This is an obvious matter and has been so fully dealt with during the past few years that we will not waste time in discussing it now.

The feature of Dr. Snell's article is to show that in the summer of 1906, in Coventry, flies had a great deal to do with the prevalence of infantile diarrhea and the consequent high death-rate among infants in that city. During most of the summer of 1906, the weather was exceptionally hot and dry, rainfall being very far below the average, while bright sunshine was greatly above the average. Indeed, given other favorable conditions, the weather was ideal for the propagation and dissemination of flies. It appears, from Dr. Snell's account, that other conditions were present in Coventry, such as manure pits, private slaughter-houses, offensive rag and bone businesses, and any amount of dust. When it is said that these conditions were present, it should be understood that three wards of the city had a practical monopoly of these nuisances, and it was in these very wards that a high death-rate prevailed. Within this area there is stated to have been a veritable plague of flies; "it was quite impossible for the householders to pick up any food which had not immediately before been covered with flies; to keep food or milk uncontaminated, in such circumstances, would have been impossible."

Therefore, Dr. Snell concludes, and it appears he has ample justification for this conclusion, that flies, the presence of which in such numbers was due to unsanitary conditions, were responsible to a very large extent for spreading disease among the young children of this ill-savored quarter. He likewise holds the view, that a case of this sort goes a long way towards the theory that unsanitary surroundings, *per se*, do not bulk largely in the causation of infantile mortality.

OMENTOPEXY.

Operative treatment for ascites, due to cirrhosis of the liver was suggested by Drummond and Morrison in 1896, and by Talma in 1898. Their idea was to establish a collateral circulation between the visceral peritoneum of the omentum, liver, and spleen and the parietal peritoneum in order to relieve the portal congestion. To-day the general belief is that the operation also gives relief by causing more or less obliteration of the peritoneal cavity, and by increasing the supply of arterial blood to the surface of the liver, which tends to nourish and maintain the utility of many of the liver cells near the surface.

In recent years the operation has become recognized as a procedure which is usually followed by more beneficial results than the older method of frequently repeated tappings. That it may not come into disrepute, this surgical treatment should not be employed indiscriminately, but only in certain cases of ascites. In the December, 1907, number of the *Practitioner*, Ketchen and Thomson considered the conditions suitable for omentopexy. They first draw attention to the causes of the ascites, attributing it not solely to an obstruction of the portal circulation, but partly to an inflammation of the peritoneum itself. If the transudation of the blood vessels were the principal factor, the natural course of the effusion would be into the lumen of the stomach and bowels, as is evident from the anatomical distribution of the vessels; furthermore, experimental ligature of the portal vein is not immediately followed by an effusion into the peritoneal cavity. Ketchen and Thomson recognize two clinically well-defined classes of cases in which ascites is associated with cirrhosis of the liver. In the first class, the presence of free fluid in the abdominal cavity is an early sign, showing itself at a stage when there are not many symptoms of general systemic poisoning. These patients stand tapping well, and show improvement after such treatment. In the second class of cases the ascites is present in the late stages, when the general systemic disturbance is well marked. These do not stand tapping well, nor do they show any improvement following it.

Having come to the conclusion that the exuded fluid in both clinical types is due to peritonitis, they offer an explanation of the clinical varieties. They hold that in the first class the peritonitis is an en-

tirely local condition caused by the same poison which produces the changes in the liver, but not dependent upon the latter. The morbid changes in the liver have not proceeded far enough seriously to impair its functional role in the metabolism of the body. Drainage of the peritoneum in these cases relieves a local condition, the inflamed peritoneal surfaces come together, and the peritoneal cavity becomes more or less obliterated by adhesions. In the second class, the liver functions are so impaired that poisons find their way into the general system, causing inflammatory changes in many organs and in the peritoneum; the peritonitis is then toxemic in origin. In these latter cases, removal of the ascitic fluid is in no way beneficial, the ascites being a symptom of a general poisoning, not a local one. It is clear that omentopexy may produce great amelioration of the symptoms in the first class of cases while it is entirely useless in the second, and of problematical value in the intermediate cases. The authors then point out the clinical symptoms from which the underlying pathological condition may be induced and so give the indications for operation. One of the first is the result of tapping. If the patient is tapped several times successfully, his general condition remaining good, it is very likely that an omentopexy will be beneficial. If, in addition there are no evidences of kidney changes, if there is no general swelling, and the enlargement of the abdomen has not been preceded by any swelling of the legs, the outlook is also favorable. On the other hand, heart disease, constant albuminuria, swelling of the legs preceding swelling of the abdomen, and a progressive deterioration of the general condition, notwithstanding paracentesis, all these contraindicate operation, which in such cases is not likely to afford much relief.

Orthostatic Albuminuria.

The question of orthostatic albuminuria is one of perennial interest and in spite of the thoroughness with which it has been studied there is still no unity of opinion in regard to it. Some authors consider it simply an increase in the physiological excretion of albumin, others regard it as a distinctly pathological process but little removed from a real nephritis. The etiology is equally uncertain, and while von Noorden assumes an abnormality of the serum albumin and calls the condition an albuminous diabetes, others explain it as due to alterations in blood pressure attending the changes in position, and still others, like Pfaundler, hold that it is an accompaniment of latent tuberculosis. The remarkable observations made by Jehle (*Münchener medizinische Wochenschrift*, January 7, 1908) on seven children exhibiting the symptoms are therefore noteworthy. He found that it was essentially the condition of the vertebral column that was concerned with the excretion of the albumin while in the upright position, and that if the child were placed so that no lordosis was caused, the vertical position did not induce albuminuria. This was effected, for example, by having the child kneel and at the same time sit on its heels, or by preventing it from assuming a perfectly erect position by connecting its neckband and a pelvic belt by a band which kept the trunk inclined forward. Under these conditions no albumin appeared, but if the body was held erect it promptly did so, while on the other hand a patient whose trunk was encased in plaster while erect continued to excrete albumin when put to bed with the jacket on. Examination of the children's spines showed that there was an abnormally pronounced lordosis at the level of the first and second lumbar vertebræ apparently due to deficient development of the musculature, and Jehle believes that through traction either on the vessels or the ureters circulatory disturbances are set up which lead to the albuminuria. This theory is especially attractive as in addition to its plausibility it offers a hopeful outlook for therapeutic endeavors directed to correction of this vice of conformation by suitable exercise, braces, etc.

The Treatment of Pruritus.

It has been said that, like eczema, pruritus forms a touchstone for testing the ability of a dermatologist, and few who have once encountered an obstinate case of this sort would be likely to belittle the difficulty of the therapeutic problems involved. Kromayer (*Deutsche medizinische Wochenschrift*, January 9, 1908) says that the lack of success frequently attending the ordinary treatment is due to the fact that this is purely symptomatic, and he describes two methods that he considers are founded on etiological principles. The symptoms of pruritus he believes is caused by the formation in the epidermis of minute vesicles which can be demonstrated and destroyed by the application of 15 per cent. caustic potash solution, brushed over the affected area by means of a pledget of cotton. In a few seconds tiny pin-head sized spots appear which on washing the surface with water swell up and resemble sago grains. These are the vesicles which owing to the thinness of their covering were more readily penetrated and destroyed by the lye. Areas of considerable size or even an entire limb may be treated in this way, the pain though severe subsiding promptly on washing with water. The tiny ulcers resulting heal in a few days under a wet dressing and a single treatment sometimes suffices to cure a pruritus of long standing. The cauterization is contraindicated so long as the area is inflamed or eczematous, is excoriated, or is weeping, and these conditions must first be relieved by symptomatic remedies. Mucous surfaces also are not suitable for the treatment. A similar result may be obtained by the use of the *x*-rays which also have the property of destroying the vesicles, though a rather intensive application is needed and the operator must not shrink from producing a mild degree of cutaneous reaction.

To Accelerate the Course of Labor.

So much has been said lately of various methods for rendering childbearing less painful by means of spinal anesthesia or the subcutaneous injection of narcotics that it is interesting to hear of another suggestion intended to shorten the process merely by mechanical measures. Landau (*Berliner medizinische Wochenschrift*, January 6, 1908) says that the duration of labor can be much abbreviated if, after it has begun and the pains are well started so that the head is firmly engaged, the obstetrician with one or two fingers dilates the cervix and endeavors to push it back over the advancing head. This is frequently repeated from time to time and has the effect of greatly stimulating the uterine

contractions so that, especially in multiparæ, the labor can be terminated in a few hours without detriment to mother or child. The procedure is intended to act mainly through the stimulation of the automatic centers in the cervical canal evoking the pains, the actual dilatation effected being of less importance. Essential conditions are that the cervix is already beginning to soften, that the head is firmly engaged so that there is no danger of distributing the presentation, and the most rigid asepsis, including the use of rubber gloves. If properly carried out Landau asserts that there is no danger of infection or laceration and he recommends the method for use in normal cases and for facilitating the complete dilatation that must precede the application of forceps.

The New Hejira.

On Sunday, January 26, 1908—it is important to note the exact date, for neglect to do so when Mohammed moved to Medina from Mecca has been a cause of much acrimonious dispute in the Muslim world—the Rev. Mother Mrs. Mary Baker G. Eddy, the "discoverer and founder of Christian Science," as the press agent of the sect officially designates her, changed her domicile from Concord, N. H., to Boston, Mass. There is nothing especially worthy of comment in this, for Boston is a much more lively town than Concord, and it is not surprising to learn that Mrs. Eddy prefers to live there. But what is interesting is the fact that she took with her on the journey a practising physician, just as many other persons of advanced years, failing strength, and ample fortune are wont to do when traveling. It is well known that Science healers often keep a licensed physician within call to sign the death certificate when malicious animal magnetism gets the better of their demonstrations, but it is not likely that any of the Mother's companions was in danger from her ministrations during the brief journey. It is evident, therefore, that Mrs. Eddy took a physician along just as any other frail old lady might have done, in order to avail herself of his services in case of need. She seems to be a wise and prudent person unwilling to take the chances of accident or sudden disease when surrounded only by a carful of her own foolish followers.

News of the Week.

Scientific Temperance Federation.—This organization, at its annual meeting just held in Boston, received reports showing that during the year its collection of scientific and other data on the alcohol question has been increased by the addition of over 1,000 books, pamphlets, abstracts, and references. This special library, regularly catalogued and indexed, is held at the disposal of every organization, student, or social worker desiring information on the alcohol and narcotic questions. The secretaries reported also the preparation and publication of over 1,200,000 pages of scientific and educational matter relating to this special subject; a correspondence of more than 6,000 letters to all parts of the United States and to thirteen foreign countries; and the issuing of a press circular containing scientific facts to editors representing a wide range of interests and several millions of readers. The officers elected for the ensuing year were: *President*, William C. Lilley, Pittsburg, Pa.; *Vice-President*, Mrs. S. S. Fessenden, Boston; *Recording Secretary*, E. L. Transeau, Boston; *Corresponding Secretary*, Cora F. Stoddard, Boston; *Treasurer*, Robert H. Magwood, Boston. The directors are: Dr. T. D. Crothers, Hartford, Conn.; E. O. Taylor, D.D., Boston; Mrs. A. J. Gordon, Boston; Dr. T. Alex. MacNicholl, New York; John Herbert, Esq., Boston; W. A. Mowry, Ph.D., Hyde Park, Mass.; John Marshall Barker, Ph.D., Boston; Rev. Richard Wright, Cambridge, Mass. The headquarters of the Scientific Temperance Federation are at 23 Trull street, Boston, Mass.

International Tuberculosis Congress.—A meeting of the Executive Committee of the New York State Committee on the International Congress was held in the New York Academy of Medicine, Saturday, January 11. The Committee outlined a plan for the enlargement of its membership and for stimulating interest in the objects of the Congress in all parts of the State. The membership of this Committee is as follows: Dr. Alfred Meyer, New York City, *Chairman;* Dr. H. D. Pease, Albany, *Secretary;* Dr. Thomas Darlington, New York; Hon. Homer Folks, New York; Hon. Robert W. Hebberd, New York; Dr. Veranus A. Moore, Ithaca; Dr. J. H. Pryor, Buffalo. The Committee will meet in Albany in connection with the public meeting on tuberculosis to be held in Harmanus Bleecker Hall, Monday evening, January 27, at which addresses will be made by Governor Hughes, Professor Welch, of Baltimore, and other prominent men. Ex-Ambassador Choate will preside.

An Antituberculosis Meeting was held in Albany on Monday evening, in connection with the meeting of the State Medical Society, under the auspices of the State Charities Aid Association and the State Health Department. Governor Hughes, Lieutenant-Governor Chanler, Joseph H. Choate, Health Commissioner E. H. Porter, and others spoke. Prof. William H. Welch of Johns Hopkins University was also present and spoke. Secretary Homer Folks read a letter from President Roosevelt expressing regret that he could not be present, but asserting his great interest in the work of the association. The President sent the assurance of his interest, sympathy, and approval in the work the association had undertaken to organize local effort for the prevention of tuberculosis in the State of New York, outside of New York City.

Movement to Check Tuberculosis in Illinois.—Physicians throughout Illinois are urging the passage of the Glackin Bill, enabling cities and villages to establish public sanatoria for the treatment of consumption. The measure, which recently passed the Senate, and is now on second reading in the House, aims to arrest the progress of the disease by affording all communities a chance to combat tuberculosis by giving the latest scientific treatment free to all inhabitants afflicted with the disease.

Fresh Air School.—A "fresh air school" has been opened in Providence, R. I., under the auspices of the Rhode Island League for the Suppression of Tuberculosis. It will be held in a room with large windows on three sides which will be kept open much of the time, the children not removing their wraps and being provided with foot warmers to keep their feet warm.

Trenton's Water Supply.—The committee appointed to investigate the recent typhoid fever epidemic in Trenton, N. J., in a preliminary report to the Common Council has recommended the appropriation of $2,500 to be used by the Board of Health in obtaining expert opinions in regard to the water

supply of the city and the best means of improving it. The committee says that it is highly probable that the Delaware River must continue as the source of water supply for Trenton, but that it has been demonstrated that this water is contaminated with sewage.

Parasites in the Appendix.—Dr. M. Clayton Thrush writes that he has received from Dr. Perry B. Preston, Superintendent of the Paraiso Hospital, C. Z., Panama, a letter referring to Dr. Thrush's article on Appendicitis Due to Oxyuris Vermicularis which appeared in the MEDICAL RECORD of December 28, 1907, and describing two cases bearing on this subject. In one of these at an autopsy on a yellow fever patient a live *Ascaris lumbricoides* and a live *Trichocephalus dispar* were found in the appendix, which showed no signs of inflammation, and in the other at an operation for appendicitis a live round worm was found in the appendix.

Catarrhal Conjunctivitis at Annapolis.—An epidemic of pink eye has broken out among the midshipmen at the Naval Academy, at Annapolis, and over seventy-five cases have been under treatment.

Plague in China.—There have been four deaths by the plague a short distance west of Hwang-hien, in the province of Shantung.

Makes Doctors His Victims.—Several Harlem physicians last week received visits from a well-dressed young man who called to inquire whether the doctor had treated a woman who had been injured in an automobile accident a few days before. When the young man took his leave some of the doctor's movables usually went with him.

Physicians' Building for Cleveland.—A number of the physicians and dentists of Cleveland have announced the plans for a million dollar building to be erected by them exclusively for professional purposes. The structure will be fifteen stories in height and is to be erected in Euclid avenue near East Ninth street.

Druggist Convicted.—A druggist having a store on Third avenue, Brooklyn, was last week convicted in the Court of Special Sessions, on evidence furnished by the King's County Medical Society, of practising medicine without a license, and was sentenced to ninety days' imprisonment in default of a fine of $500.

The Nicholas Senn Estate.—Letters of administration were issued recently by Probate Judge Cutting to Dr. E. J. and Dr. William Senn, sons of the late Dr. Nicholas Senn. Dr. Senn died intestate, leaving property valued at $180,000. Of this amount, $150,000 is in personal property. The administrators filed bonds of $300,000. The estate will be shared by the sons and the widow. An estate of $402,000 in Wisconsin was also left by Dr. Senn, acording to the petition of his sons. Most of the Wisconsin holdings are scheduled as personal property, being mortgages on real estate.

Emergency Hospitals in Chicago.—A system of emergency hospitals for the care of persons injured in accidents will undoubtedly be in operation in Chicago within six months, according to the present indications. The plan now under consideration involves a joint arrangement between the county and the city, whereby the former will operate the emergency hospitals and care for the victims of accidents in all parts of the city, while the latter will have jurisdiction of all cases of contagious diseases. The system of hospitals it is proposed to establish includes a central hospital within the loop district; branch hospitals at the Stock Yards, South Chicago, and in the northwest and southwest quarters of the city; certain private hospitals in other sections to be authorized to care for the victims of accidents at the expense of the county.

Bequests by Dr. Ordronaux.—More than half of the estate of $300,000, left by the late Dr. John Ordronaux, of Glen Head, L. I., is bequeathed to charitable and educational institutions. The bequests include $6,000 to the Nassau Hospital Association for the endowment of a bed, $6,000 to the Jamaica Hospital for the same purpose, and $6,000 to the Flushing Hospital; Dartmouth College, $30,000; Mary Hitchcock Hospital, $6,000; University of Vermont, $10,000; Trinity College, Hartford, $10,000; George Washington University, $5,000; Little Sisters of the Poor, New York City, $5,000; Old Colony Historical Society, $1,000; Marton Hospital, Taunton, Mass., $6,000; Boston University, $2,000; Columbia University, New York City, $3,000; destitute blind of New York City, $5,000; Children's Aid Society, New York City, $5,000; Industrial Christian Alliance, New York City, $5,000.

Gifts to Mount Sinai Hospital.—At the meeting of the officers of this hospital last week a gift of $6,000 to the endowment fund was announced and it was stated that other gifts during the last year had amounted to $18,892.12. The total income in 1907 amounted to $351,837.19 and the expenses to $383,057.48. During the year 6,173 patients were admitted, and 177,829 were treated in the dispensary.

Railway Casualties.—According to last bulletin of the Interstate Commerce Commission there were more than 21,000 casualties on the railroads of the United States in the three months ended September 30, 1907. The exact figures were 1,339 killed and 21,724 injured. This is an increase of 157 in the number killed and 3,056 in the number injured as compared with the corresponding period of 1906. The total number of collisions and derailments in this quarter was 4,279, of which 320 collisions and 222 derailments affected passenger trains. The damage to cars, engines, and roadway by these accidents amounted to $3,605,696.

New York's Birth Rate.—The vital statistics of the Board of Health for 1907 show that during that year there were 125,126 births in the city, as against 111,772 in 1906, the gain being the greatest since 1847. The rate is now 40 per cent. higher than that of Paris. The deaths were 79,205, equivalent to a rate of 18.48, and about 3,000 in excess of those of 1906.

A Conviction for Exposure to Contagious Disease.—A nursemaid employed in a family living in this city was last week found guilty in the Court of Special Sessions of violating section 143 of the Sanitary Code in taking a child into a house occupied by a person suffering from a contagious disease. It was charged that on January 15 the girl took one of her employer's children to the house of her sister who had a daughter ill with scarlet fever. Sentence was suspended.

Died at One Hundred and Twenty.—Mrs. Mary Ramsey Wood, a native of East Tennessee, has died in Bristol, Va., at what is claimed to be the well authenticated age of one hundred and twenty years.

The "New York Polyclinic Journal."—After an interval of ten years the publication of this monthly

is to be resumed under the editorship of Dr. Charles H. Chetwood.

The Kerr, Kendall, Gillespie, and Bandera Counties (Tex.) Medical Society.—The following officers for this society were elected at the meeting held in Kerrville on January 14: *President,* Dr. F. L. Fordtran; *Vice-President,* Dr. R. L. Combs; *Secretary and Treasurer,* Dr. A. K. Tainter.

Central Medical Association of Oklahoma.—This association met in Enid, on January 14, and elected the following officers: *President,* Dr. J. H. Barnes of Enid; *Vice-Presidents,* Dr. J. B. Young of Oklahoma City and Dr. E. D. Seabright of Carmen; *Secretary-Treasurer,* Dr. J. B. Cullom of Hennessey.

Dubuque County (Ia.) Medical Society.—The following were elected as officers for this society at the meeting held in Dubuque on January 14: *President,* Dr. James Alderson; *Vice-Presidents,* Dr. A. H. Blocklinger and Dr. Reiner; *Secretary,* Dr. H. G. Langworthy; *Treasurer,* Dr. Lillie Kinnier.

New Haven Medical Society.—The election of officers of this society, held at the meeting on January 18, resulted as follows: *President,* Dr. Edw. M. McCabe; *Vice-Presidents,* Dr. A. N. Alling and Dr. M. H. Steele; *Secretary,* Dr. E. R. Whittemore; *Treasurer,* Dr. R. E. Peck.

North St. Louis Medical Society.—This society has elected officers as follows: *President,* Dr. H. J. C. Sieving; *Vice-President,* Dr. A. A. Henske; *Secretary,* Dr. H. J. Niebruegge; *Treasurer,* Dr. A. F. Koetter.

Whatcum County (Wash.) Medical Association.—Officers as follows were elected at the meeting of this society held on January 13: *President,* W. H. Hunt; *Vice-President,* Dr. Keyes; *Secretary,* Dr. Torney; *Treasurer,* Dr. Jacob Smith.

Memorial Service for Dr. Senn.—On February 2 there will be services in memory of Dr. Nicholas Senn, at the Fine Arts Building, Chicago. President James, of the University of Illinois, will preside.

Obituary Notes.—Dr. John Ordronaux of Glen Head, L. I., died of apoplexy, on January 20, at the age of seventy-seven years. He was born in New York City and was graduated from Dartmouth College with the class of 1850, from Harvard Law School two years later, and from the National Medical School in 1859. From 1872 to 1882 he was a member of the State Commission in Lunacy and he was the author of numerous works on medical jurisprudence. Since 1861 he had been a lecturer on medicolegal subjects in the Columbia University Law School, Dartmouth College, University of Vermont, and Boston University.

Dr. Robert S. Blakeman, Assistant Surgeon, U.S.N., retired, died suddenly, on January 22, in the naval hospital at Norfolk, Va. Dr. Blakeman, who was obliged to retire because of failing eyesight, distinguished himself in active service during the war with Spain, being on the cruiser *Boston* in the battle of Manila Bay.

Dr. Frederick A. Burrall, formerly of this city, died at White Plains, N. Y., on January 21, in his seventy-fifth year. Dr. Burrall was a graduate of Williams College and of the College of Physicians and Surgeons, and in 1857 was a member of the Faculty of that institution. He was a member of the Academy of Medicine.

Dr. David A. Hoffman of Oskaloosa, Ia., died on January 13 at the age of eighty-one years. He was born in Jackson County, O., and received his medical training under Dr. William Blackstone of Athens and at the Western Reserve College, in Cleveland, from which he was graduated in 1848. Since that time he had continued in active practice until a few weeks ago. He was well known as a geologist and archeologist and his collections in these sciences were very large and valuable.

Dr. August Rodch of St. Louis, Mo., died on January 14 of apoplexy, at the age of eighty years, while making a professional visit. He had practised in St. Louis for nearly sixty years, continuing in active work in spite of his advanced age.

Dr. M. L. Banks of Columbia, Miss., died on January 9 at the age of seventy-six years. He was born in Westville, Miss., and had practised in Columbia for nearly fifty years.

Dr. William Terry of Ansonia, Conn., died on January 14 at the age of eighty-six years. He was born in Enfield and had practised in Ansonia since 1860. During the Civil War he served as assistant surgeon in the Army Hospital at Alexandria.

Dr. J. Eugene Kelly of New London, Conn., died in Springfield, Mass., on January 18, at the age of thirty-nine years. He was born in Canada, and, after spending his boyhood in Pittsfield, Mass., was graduated in medicine from Albany Medical College. After practising for a time in Pittsfield he removed to New London.

Dr. Henry W. Painter of North Haven, Conn., died on January 16 at the age of seventy-six years. He was graduated from Yale Medical School in 1856 and for many years practised in West Haven. For the past fifteen years he had lived in North Haven.

Dr. Paul C. Esbjorn of Rock Island, Ia., died in Chicago, after a surgical operation, on January 18. He was born in Sweden, in 1870, but was brought to this country while a child and was graduated from Augustana College in 1894; later he received his medical degree from the State University and practised for a time at Stafford, Ia. Ill health compelled him to give up active work about a year ago.

Dr. Asa W. Wilkinson of this city died, on January 25, at the age of seventy-five years. He was born near Cayuga Lake, N. Y.; was graduated from Brown University, and studied medicine at the New York Medical College, taking his degree in the '50s. After hospital service here he engaged in chemical technology and became assistant to Prof. R. Ogden Doremus at the New York Medical College and afterward at the Bellevue Medical College and the College of the City of New York. Dr. Wilkinson was well known for many improvements he made in the manufacture of illuminating gas.

Dr. Percival E. Lodge died at Philadelphia, on January 19, at the age of fifty-five years. He was graduated from Jefferson Medical College in the class of 1875 and he subsequently served as resident physician in the Philadelphia Hospital. He was for twenty years police surgeon and for ten years professor of anatomy in the Pennsylvania College of Dental Surgery.

Dr. Patrick M. Kelly died at Philadelphia, on January 20, at the age of seventy-four years, after a protracted illness. He was graduated from the Philadelphia College of Pharmacy in 1879 and from the medical department of the University of Pennsylvania in the class of 1881.

THE FIFTH HARVEY SOCIETY LECTURE.

The fifth of the present series of lectures given under the auspices of the Harvey Society was delivered in the Academy of Medicine on Saturday, January 25, in the presence of a large audience. The speaker was Professor George W. Crile, of Western Reserve University, and the subject was "Shock."

Before beginning his address the speaker demonstrated a number of instruments which he had found very useful in performing direct transfusion of blood. These, he stated, were modeled largely after some of the instruments used by oculists and by jewelers. He would not dwell on the pathology of shock, nor on the very interesting series of experiments which had led him to adopt the present line of treatment. These phases of the subject would be found discussed in a number of papers published by him in the past few years. The speaker would take it for granted that his auditors were familiar with the views there expressed, and would pass on to the differential diagnosis of shock and hemorrhage. The diagnosis of these two conditions could often be cleared up by an examination of the blood, especially as to the hemoglobin and as to the leucocytes. In hemorrhage, after a time, there was usually a drop in the hemoglobin and a moderate leucocytosis. In shock there was little change in either. The essential causes of shock were, of course, a fall in the blood pressure and a functional breakdown of the vasomotor center, due to excessive afferent stimuli and to anemia. It was apparent that after a time a vicious circle was thus established. The speaker said there was a strong psychic element in shock, and described in detail a number of procedures to guide the surgeon and the nurse in managing the patient before an operation. There were cases in which attention to these details, trivial as they might seem, would mean the saving of the life of the patient.

It was readily understood that, as shock was largely caused by an insufficient blood supply of the vasomotor center, the combination of shock and hemorrhage was very grave. This, however, was a common combination and it demanded that the surgeon understand thoroughly all the ways of combating the conditions. Up to three per cent. of blood could be lost by an average healthy adult, without any apparent effect. In infancy and old age, however, the proportion was much less. The technique of the surgeon then should save the blood supply as much as possible. The choice of anesthetics was also of considerable importance. Nitrous oxide produces a considerable rise of blood pressure, and therefore could not well be used in cases associated with much hemorrhage. Chloroform produced less rise of pressure than did ether, but in this country at least it was feared because of its occasional harmful effects. Rough work about the skull, such as chiseling instead of drilling, was also productive of shock. There should be less blunt dissection. All of these things increased the afferent stimuli to the already overtaxed vasomotor center. In operations about the mouth, pharynx, or larynx, it was well to cocainize the mucous membrane prior to the operation, thus shutting off these afferent impulses. A dose of atropine should also be administered. The speaker described several cases in which he had operated about the larynx and caused the production of symptoms of shock by his manipulations on the mucous membrane. Since he had learned the cause of the symptoms, and had cocainized the tissues, he had had no such accidents.

Dr. Crile then discussed the technique of operations about the thorax, in the abdomen, and on the lower extremity. Each of these had its peculiarities so far as shock was concerned. It was curious that the upper part of the abdomen was more sensitive in this respect than the lower part. He warned against undue exposure of the intestines in abdominal operations. It was surprising how much good could be accomplished by the injection of morphine shortly before an operation. This procedure was especially valuable in operations in the abdomen. He had not seen this give rise to temporary paresis of the gut as was feared by many surgeons. Cocaine should also be used more in operations to check the excessive afferent impulses from the site of operation. A one-tenth of one per cent. solution would often do wonders.

So much, then, for the ways of preventing or diminishing shock. The question often came up whether, in cases of traumatic shock, one should operate during shock, or wait until the patient had come out of that condition. The answer to this would depend on whether one could successfully block the afferent impulses, as just described, and whether one had facilities for doing a direct transfusion. If either of these were possible, he would prefer to operate at once. The speaker criticised the various methods of combating shock, which had been in current use even up to a short time ago, and were still largely relied upon by those ignorant of the essential nature of shock. Overstimulation was worse than useless. What the vasomotor center needed was rest, and an increased blood supply. The injection of morphine, therefore, was good, and to this should be added a head-down posture. If possible the pneumatic rubber suit should be applied, or at least the patient's limbs should be tightly bandaged. After all, however, the final treatment of shock was direct transfusion of blood.

The speaker then described in detail his technique for direct transfusion. The first requisite was to secure a suitable donor. He had found that this was a simple matter. There was, so to speak, a psychological moment in which to broach the subject to a prospective donor. This was directly after he had left the bedside of the patient, and was still full of sympathy. A few words as to the gravity of the case, and of the one possibility of saving the patient's life, usually brought forth a voluntary offer on the part of the friend. If not, the explanation that the process was free from pain and from all danger to the donor would probably bring the required answer.

The suitability of the donor's blood should be tested, as now and then normal hemolysins were present and caused considerable disturbance. These hemolysins were frequently present in cases of malignant tumors. Thus in thirty cases with such tumors which he had examined, he had found hemolysins present twenty-six times. The patients were placed on tables side by side, but with heads in opposite directions. The arms were placed on a table between the patient and donor, and then the process of transfusion was performed. Cocaine was the anesthetic, a solution of one-tenth per cent. being infiltrated into the tissues.

The technique of the operation was described in detail. The transfusion ordinarily took about one hour. The improvement in the patient was remarkable, and was usually noticeable within ten minutes after the beginning of the transfusion. The heart

beats became stronger, the breathing fuller and slower, the color of the lips returned, the eyes became brighter, and the mental state cleared up. Direct transfusion was the one great treatment for shock; it could not be replaced by transfusions of physiological salt solution, or of so-called artificial serum. In closing, Dr. Crile gave a description of a desperate case in which he had successfully employed transfusion.

Dr. Joseph D. Bryant moved the thanks of the society to the speaker, after which the chairman announced that the next lecture in the series would be delivered on February 9 by Professor Joseph Jastrow, the subject being "Subconsciousness."

Correspondence.

ACETATE OF ALUMINIUM OR ACETATE OF AMMONIUM?

To the Editor of the Medical Record:

Sir:—In Dr Morton's excellent article on the "Treatment of Chancroidal Bubo" in the Medical Record of January 25 there occurs what seems to me an error, which it would be a pity to let go uncorrected. In two places Dr. Morton mentions fomentations with solution of acetate of *ammonium*. The author mentions that he saw the method employed in the Charité in Berlin. As solution of acetate of ammonium is not used for fomentation purposes at the Charité or at any other German hospital that I am familiar with, while solution of aluminium acetate (the old well-known Solutio Burrowi) *is*, I believe it is the latter that the doctor had reference to.

It might also be stated that solution of ammonium has no resolving, antiphlogistic, or antiseptic properties. On the contrary, its application to an inflamed surface would in many cases prove irritating. Solution of aluminium acetate, on the other hand, is one of our best media for applying compresses; mildly antiseptic, non-irritating, cooling, and resolvent.

William J. Robinson, M.D.

A CHILDREN'S HOSPITAL BRANCH OF THE ANTI-NOISE SOCIETY.

To the Editor of the Medical Record:

Sir:—A few weeks ago you were kind enough to call attention to the ordinance establishing "quiet zones" for hospitals and to the "hospital street" signs about to be erected by the city. These signs are now being rapidly put in place and have already been effective in materially reducing the suffering of our hospital inmates from unnecessary noise. Almost every institution with which I have communicated has assured me that a marked improvement has already taken place, while from a few the reports are most gratifying, as from the German Hospital, whose superintendent states that "In the ten years that I have been in this place I have never known such quiet." The willingness of many to help the sick, now that their attention has been directed to the matter, is shown in a variety of ways, of which many touching proofs reach us.

The action of the city in creating "hospital zones" will probably be more successful in quickly reducing the unnecessary noises of traffic and manufacture than in immediately suppressing the boisterous pastimes of children. Youth is forgetful, and until we can touch the heart of the child and make it understand what pain its own individual acts can cause the sick we must not be surprised if the hospital ordinance is frequently disregarded. Therefore, in our efforts to leave nothing untried which might relieve our sick, we have now taken steps to form a "Children's Hospital Branch" of our society, the members of which will wear button badges and will promise not to play near hospitals or other places where illness is known to exist. We both hope and believe that this movement will be of, at least, as much benefit to the child as to the patient, and that the thought that it can be, as it were, a protector of the sick will touch its heart and elicit its sympathy.

In order to ascertain whether we were right in believing that this junior branch would be of importance to children as well as to hospital inmates, we consulted a number of public men, city officials, educators, divines, physicians, and hospital superintendents, and from one and all received the most gratifying encouragement.

Among those who have earnestly supported the plan to secure the cooperation of the children I may mention Dr. Thomas Darlington, President Nicholas Murray Butler of Columbia University, Dr. William H. Thomson, Dr. Thomas L. Stedman, Mr. Richard Watson Gilder, Rev. Dr. J. M. Haldeman, Rev. Dr. Merle Wright, Rev. Dr. Parkhurst, Rev. Fr. George M. Searle, C.S.P., Superior General of the Paulist Order; Rev. Percy S. Grant, Rev. Henry M. Stimson, Rev. H. Pereira Mendes, Professor George W. Jacoby, M.D.; Rev. Dr. Silverman, and many others. As for the superintendents of hospitals, they have eagerly welcomed this hope of relief for their suffering charges.

With such endorsement we felt that we were in a condition to place the matter before the Board of Education and ask it to bring our junior league to the attention of the pupils in the public schools. The Board has cordially endorsed the plan and at a meeting held January 8 passed a resolution directing the City Superintendent to urge upon the principals of the high and elementary schools their hearty cooperation in arousing the interest of the pupils in the proposed Children's Hospital Branch.

The badges are now being made and will probably be ready for distribution in a few days. On a white ground will be a buckled band in blue, inclosing the word "Humanity." Above it will be "Children's Hospital Branch," and beneath it "Society for the Suppression of Unnecessary Noise."

It is our sincere hope that the press, which has hitherto given us such splendid encouragement and assistance, will once more lend us a helping hand in our efforts to relieve the sick, while teaching the young the beauty of thoughtfulness for others and encouraging in it the desire to lighten the suffering of the afflicted. All must rejoice in the conviction that through their own efforts the burden of the world's wretchedness has been somewhat lessened.

Mrs. Isaac L. Rice.

INSTRUCTION IN HYDROTHERAPY.

To the Editor of the Medical Record:

Sir:—Dr. Simon Baruch in his paper on 'Instruction in Hydrotherapy," which appeared in the Medical Record of January 18, makes the following statements: "Columbia University is the first to inaugurate a special course by a special chair of hydrotherapy," and again, "Happily Columbia University has taken the initiative in this movement for the betterment of our therapeutics." It is only just that it should be known that Dr. William H. Diffenbach, himself a pupil of Winternitz, has for several years conducted an admirable course in hydrotherapy in the New York Homeopathic Medical College.

OUR LONDON LETTER.

From Our Special Correspondent

HEALTH OF NAVY—ROYAL SOCIETY OF MEDICINE—SUPPORTS OF THE PELVIC VISCERA—DIGITALIS—INTERSTITIAL KERATITIS—TYPHOID CARRIERS—BENINDEN SANATORIUM—OBITUARY.

London, January [illegible]

The report issued yesterday on the health of the navy in 1906 is most satisfactory, for it shows a continuous improvement. Not only are the case, invaliding, and death ratios for the year lower than the averages for the previous nine years, but the average loss of service for each person has fallen from 12.79 to 10.60 days, and the year's ratios, under each heading, are the lowest recorded since 1856. The medical statistical returns show the ratios per 1,000 of all classes of disease and injury entered on the sick list, as well as the invaliding and mortality from the different forms of disease and injury at the various stations during the year.

The Royal Society of Medicine continues to attract the attention of many without as well as within its Fellowship, as the fifteen sections comprise such a wide range of subjects. Some of them indeed have once or twice proved less interesting than the societies to which they have succeeded, but the majority have maintained a high level at each meeting.

The Obstetrical and Gynecological Section has had a discussion on the supports of the pelvic viscera, begun by Dr. W. E. Fothergill, who in a lucid paper maintained that the current teaching of anatomy in relation to gynecology, though correct in a general sense, is not sufficiently accurate, because the teachers take their anatomical statements from the writings of professed anatomists. But he showed that recent papers by anatomists of the highest rank proved that their views have changed in a way exactly parallel to

that in which clinical gynecology has moved. The utero-sacral ligament is a mere peritoneal fold; the broad ligament a mesosalpinx and mesoovarium; the round ligament a vestigial structure, as are also the muscles of the pelvic diaphragm. In the same way other points go to prove that the old views on uterine supports are untenable and that the uterus is mainly supported by the perivascular connective tissue bundles above the pelvic floor.

The president, Dr. Herbert Spencer, thanked Dr. Fothergill for his interesting paper and mentioned some particulars in relation to the subject to be observed in operations. Dr. Amand Routh thought the author had proved his contention that the uterus was mainly supported as he had stated, and he hoped the new view would be generally accepted.

Dr. Paramone disagreed with the author and said we must consider not only the structures which united the uterus to the pelvic wall and floor, but the intraabdominal pressure, which depended on the capacity of the cavity, the volume of its contents, and the condition of the boundary muscles. The fact that the uterus does not change its form from complete rupture of the perineum had been pointed out by Matthews Duncan, and if prolapse occurred other factors must be brought into play.

If intraabdominal pressure is much increased through deposit of fat, the uterus may be often found high up on account of the activity of the levator ani. If in such a case the pelvic floor gets damaged during parturition, prolapse is sure to follow.

Dr. Briggs thought too much had been attributed to ligaments. The muscular and fibrous tissues around joints controlled their movements. The ligaments of the pelvic viscera were insignificant in comparison with the mass of muscles, fascia, and fibrous packing.

Sir Arthur Macan remarked that the importance of the pelvic connective tissue was shown years ago by Freund, and lately a band on each side of the cervix had been differentiated by Kocks as the *pars cardinalis lig. lati.* The effect of the loss of support below could often be seen when prolapse of the anterior vaginal wall followed rupture of the perineum. It dragged the cervix downwards and forwards, producing backward dislocation of the fundus and finally prolapse. Senile atrophy of the pelvic connective tissue would also produce prolapse by taking away the natural support. The strength of the support from below might also be seen in the resistance to the expulsion of the head in labor.

In the Therapeutical Section the action of digitalis in cardiac cases has been considered in an able paper by Dr. James Mackenzie detailing clinical observations illustrated by a series of tracings. He also showed a heart dissected so as to display clearly the auriculo-ventricular bundle. The results of experiment on animals, he thought, should only be cautiously accepted. In man, he said, the effect of the drug was altogether dependent on the lesion involved. If dilatation was absent and the tonicity of the heart preserved, digitalis would do no good. If the heart was of normal size, dropsy was not of cardiac origin. The irregular pulse of mitral disease he held to be due to a ventricular inception of the heart-beat.

In reply to a question, Dr. Mackenzie said he found as a rule that the changes in tracings due to the drug did not become noticeable for about ten days.

Professor Cushny testified to the great value of these careful bedside observations and the difficulty of experimental research. With the same dose of digitalis given to the same animal, in just the same way there were great diversities in the results.

The Society for the Study of Disease in Children (sometimes jocosely alluded to as the "childish society," more often briefly as the Children's Society) has been engaged in an important discussion on inherited syphilis. The subject is so extensive that only one point can be considered at a time. Mr. Sydney Stephenson contributed a paper on interstitial keratitis, based upon 101 cases. In them he found signs of inherited syphilis in 69.3 per cent., of tubercle in 9.9 per cent., and four cases were due to acquired syphilis. Four-fifths of the patients were aged from five to fifteen, showing how essentially it is a disease of childhood, although cases had been reported as late as thirty-eight years. Of the 101 cases 61 were in females. The symptoms were less typical in the very young. In one of Mr. Stephenson's cases there was an interval of seven years before the second eye was attacked. Ulceration of the cornea had occurred in four of his cases. The term interstitial keratitis is inexact, as the ailment is primarily an inflammation of the tissues of the ciliary body. From this it spreads forward to the iris and deeper layers of the cornea, and backward to the anterior parts of the choroid. Mr. Stephenson insisted on the necessity of grasping this view in order to understand some of the clinical features, *e.g.* the hypopyon often present, and which of course represents exudation from the inflamed ciliary body which has passed through the pupil and so gained the anterior chamber.

The discovery of the *Treponema pallidum* as the specific cause of syphilis and the production of the disease experimentally go far to establish that interstitial keratitis is due to the lodgment and multiplication of the organism in the cornea, where it is dormant until some exciting cause lowers the resistance of the part and so precipitates the attack.

Plastic roentgenography is the pretty term proposed for producing the plastic effects described by Bela of Késmark and which Dr. David Morgan explained with photographs and lantern slides at the Liverpool Institute on the 12th ultimo. Dr. Morgan further demonstrated the plan of inflating the bladder with oxygen for diagnosis with *x*-rays. He showed a photograph of a stone obtained by this plan. The structure of the stone and the outlines of the bladder were well displayed. The transparency of oxygen, he said, rendered any irregularity of the vesical mucosa readily discernible, so that the method should prove useful in the diagnosis of various vesical troubles.

Dr. Davies, Municipal Officer of Health for Bristol, has been for some time engaged in conjunction with a Home Office Inspector in endeavoring to discover the source of a continuous series of typhoid cases in the Brentry Home. From September, 1906, to last November there were 28 cases—two fatal—which could not be accounted for. Dr. Davies now reports that the facts seem to show that a "carrier case" of chronic typhoid intermittently infecting food or milk has been the source of the trouble. A woman who had the disease six years ago seems to have been a "typhoid carrier." She was isolated on November 13 and the last case at the institution was on the 24th, quite within the incubation period, and no case has occurred since. Some German cases, one in New York and one in Scotland, are quoted by Dr. Davies as the only other successful investigations known on this line of research.

The Beninden Sanatorium for Workmen, supported by trades unions and others, opened in March, as I informed you at the time, claims some success. The association which established it has issued its first report. From this I find that 67 cases were admitted up to October 1. Of these, 36 were completed and 31 remained in the sanatorium. Of the 36, there were 29 of pulmonary consumption, 3 doubtful and 4 were cases of other diseases. The 29 are divided into three classes—(a) early cases, eleven in number, all gained weight and returned to work; (b) five moderately advanced cases, whose stay averaged eleven and a half weeks, and four gaining in weight; (c) thirteen advanced, whose stay averaged nine weeks each; of these, five improved, seven did not, and one died. It is remarked of these that, though too far advanced for the disease to be arrested, the patients had learned the best way to live to alleviate their sufferings and to avoid being a source of danger to others.

Dr. John Roberts of Chester died last night at the age of 66. He was a magistrate and alderman, had served the office of mayor and was widely esteemed. He had practised for some forty years in Chester and had been identified with most of its medical charities. He founded the Skin Dispensary. He was also the leading spirit of the Welsh community, which is large in Chester.

OUR PARIS LETTER.

(From Our Special Correspondent.)

RADIOTHERAPY OF VASCULAR NEVI—MORTALITY DUE TO ALCOHOLISM—PLASTIC RADIOGRAPHS—GUNSHOT WOUNDS OF THE EAR—POSTOPERATIVE PAROTITIS—LIGATION OF THE COMMON CAROTID—ELECTION OF PROF. LANDOUZY.

PARIS, December 15, 1907.

An interesting paper on the treatment of vascular nevi with radium by Wickam and Degrais was read before the Académie de Médecine. A series of water color drawings was shown illustrating different types of vascular nevi which had been whitened and cured by this means. They used for the purpose applicators covered with a varnish containing the radium and permitting the action to be regulated by the duration and frequency of the applications. In some instances a cure could be effected by means of mild treatments frequently repeated without causing the least reaction; in other cases, however, it was preferable or necessary to produce a more or less active reaction. In this way the tissues became soft, flexible, lost their color, and presented an excellent cosmetic effect. The easiest to cure were the lesions that were very deeply colored and those which projected some-

what. The method did not cause any pain, so that large areas could be treated and it could be applied even to young infants during their sleep.

Fernet presented an interesting report on mortality due to alcoholism in which he considered the statistics collected from 1,500 deaths. He found that alcohol was an important factor in one-third of these, the principal cause in one-tenth of the cases, and a contributing cause in more than a fifth. Among the insane it was found as a cause of death in one-half of the cases. The speaker concluded by saying that alcoholism represented a real danger to society and that it was the duty of all persons interested in public health to combat it. The following speaker, Reynier, also dealt with this question, discussing alcoholism as a factor in pulmonary tuberculosis and tuberculosis in other situations, such as the joints, Pott's disease, ostitis, and fungous synovitis. In investigating the alcoholic history of a family, it was terrifying to see the number of instances of infantile tuberculosis due to this cause. He expressed the hope that the resolutions on the alcohol question that had on several occasions been adopted by the Académie would receive more consideration from the authorities.

In the Société de Chirurgie Tuffier showed some examples of radiographs with plastic effect made by Aubourg. In preparing these a second picture, giving an image with the appearance of relief, was obtained from the ordinary radiograph, and in this way it was possible to study details of the structure of the bones and soft parts that were not ordinarily discernible.

Picqué described an interesting case of successful operation for a gunshot wound of the ear. While the older surgeons always advised against intervention in dealing with bullets in the internal ear, at present the indication was to operate in every case. The injured petrous bone was exposed to infection which might involve not only the cavities of the ear itself, but also the meninges and the brain. He discussed the various operative measures that came in question, and expressed the opinion that the posterior route was preferable to the anterior one in removing projectiles imbedded in the petrous bone. This paper was followed by an animated discussion, in the course of which Prof. Berger spoke of the value of the Trouvé electric probe in locating small projectiles. With this instrument it was possible to determine the depth from the surface, the direction, the size, etc., of the foreign body and its removal was greatly simplified. Sieur considered that the extraction of the bullet itself was not a sufficient reason for forcing the hand of the surgeon, for its discovery was frequently difficult and involved danger to the facial nerve and carotid artery. He was of the opinion that the retroauricular operation was the only permissible one. Sebileau believed that there were important reasons for immediate operation in such injuries. It was advisable to act at once in order to diminish the risk of later complications through disease of the labyrinth, etc., and also to avoid suppuration from the injured district. He preferred the retroauricular operation. The antrum should be opened widely in such a manner as to transform all the cells of the ear into a single cavity and afford room for searching for the projectile no matter where situated and also to secure subsequent drainage without danger of retention. Loison thought that the best method of determining the position of the projectile in the bony structures of the ear was to search for it with a metallic needle under radioscopic control. Reynier was in favor of prompt intervention in injuries of this type and thought that it was preferable to follow the track of the bullet in attempting its extraction. Schwartz also was of the opinion that the route of access to the projectile would vary in every case. In one instance he had been able to remove through a simple preauricular incision, involving only the skin and the temporal muscles, a ball that had entered the squamous portion of the temporal bone.

In connection with this discussion the subject of postoperative parotitis came up. Morestin described a case of this complication following a vaginal section performed on the preceding day for a pelvic abscess. The parotitis was treated by pressure on the gland by means of which the pus was evacuated through Steno's duct. This procedure carried out two or three times a day effected complete cure in about ten days. Legueu discussed the conditions under which the complication occurred; he thought that the parotitis was always of canalicular origin and that its principal cause was obstruction to the flow of secretion. This might be due to the action of the chloroform, the liquid diet, or the loss of water of the body as a whole. The conclusion to be drawn was that in order to prevent and treat the condition, the mouth should be disinfected, the gland should be massaged, and a sufficient amount of water should be supplied by infusion. The parotid secretion should be encouraged by mastication, if necessary of a sterilized bit of rubber, and solid food should be given as early as possible. Picqué had found that the postoperative parotitis usually occurred in infected or cachectic patients, and was due both to increased virulence of the buccal bacteria and to chemical changes in the saliva. In mild cases simple expression of the gland might effect a cure, but if suppuration or gangrene occurred early incision was indicated. Reynier held that the best treatment was massage with rigid buccal antisepsis. Loison had seen several severe cases in which multiple incision was required for the evacuation of the suppurating foci. Some of the patients died and the autopsy showed that the entire gland was infiltrated. Potherat said that such cases of parotitis were due to the general condition of the body. Concerning the treatment local applications and massage of the gland might be tried early, but as soon as there were signs of pus formation the only surgical method was to open the suppurating area.

The immediate results of ligation of the common carotid artery were also discussed. Lejars, who reported a case in which this artery was ligated for the removal of an aneurysm and in which death occurred, thought that the operation was a very serious one; it subjected the patient to certain possibilities, such as sudden death, or cerebral softening, that should be emphasized. Guinard thought that the dangers attending ligation of the common carotid artery were largely due to inadequacy of the anastomoses uniting the carotid systems of the two sides. At the moment of tightening the ligature about the artery there was a sudden interruption of the blood flow to the corresponding hemisphere of the brain. The operation should, therefore, never be done when the anastomotic branches had been damaged through traumatism or a previous surgical operation. Faure had ligated the common carotid ten times, and three of the patients had succumbed to prompt cerebral lesions. Accordingly, he now never performed the operation without apprehension. Quite recently a patient whose external and internal carotids he was about to tie had become hemiplegic on the operating table while the choloroform was being administered.

The term of Prof. Debove as dean of the Faculté de Médecine de Paris having expired and as he was unwilling to serve again the members of the faculty at a meeting held on November 21 nominated Prof. Landouzy for the office and he was almost unanimously elected.

Progress of Medical Science.

Boston Medical and Surgical Journal, January 16, 1908.

The Clinical Importance of the Uneven Distribution of Hydrochloric Acid in the Gastric Contents.—A. E. Taussig and W. H. Rush comment on the lack of homogeneity of the gastric contents and have made a series of investigations on a group of patients, comprising cases of gastroptosis, neurasthenia, hyperacidity, pyloric spasm, achylia, mucous colitis, and chronic gastritis. They note the following conclusions: (1) When the stomach contents are expressed and aspirated in the usual manner as completely as possible, the patient sitting erect, only a comparatively small portion of the gastric contents can be obtained. (2) After any of the usual test-meals the acidity of the portion so obtained cannot be assumed to represent the acidity of the stomach contents as a whole. (3) If, after this portion of the stomach contents has been removed, the patient is made to lie down, it is usually possible, by means of aspiration, inflation, and the like, to obtain a further considerable quantity of stomach contents. This second portion often differs considerably in its acidity from the first portion. (4) Even after this second portion has been removed, the stomach still contains considerable unobtainable residue. The amount of this is apparently independent of the total quantity of gastric contents, and probably varies from one to three ounces. (5) The quantitative determination of the acidity of the gastric contents is thus seen to be subject to a grave source of error. This will be diminished if the contents obtainable in the prone position are also examined. It will be further lessened if the acidity of the two portions does not differ very widely, since then we may assume that the acidity of the unobtainable residue will itself not be very different. (6) It follows that, in practice, trustworthy results can be obtained only if the following precautions are observed: the stomach contents must be obtained separately in the erect and in the prone posture; the acidity of each portion must be determined and diagnostic conclusions, based upon the

degree of acidity, can be drawn only if the two acidities correspond fairly well, or if the total quantity of gastric contents obtained is so great that the unknown acidity of the unobtainable residue may be neglected. (7) Indeed, the entire concept of degree of acidity of the stomach contents seems not to correspond to anything real. Different portions of the stomach contents have different degrees of acidity. We may speak of the acidity of the contents at the fundus or near the pylorus, or, at most, of the average acidity of the total contents. It is this last that clinicians have attempted to determine, with what scanty success it has been the object of this paper to show.

New York Medical Journal, January 18, 1908.

Rhythmical Alterations in the Width of the Palpebral Fissure of Both Eyes Probably Produced by Spasm of the Levator Palpebræ Muscles.—C. A. Veasey refers to a similar case recently reputed by Posey and reports the personal case of a boy seven and a half years old who had always been nervous and very quick in his movements. For some months there had been observed an upward movement of each upper lid, occurring about twenty times in a minute and sufficiently great in extent to uncover the cornea and expose the sclera above. The movements were much more marked at times than at others, but were especially bad when something occurred to make the child nervous. The movements were rhythmical in character and were in all probability due to contraction of the levator muscles. The frontalis was not involved nor were there any changes in the pupils. Occasionally there were slight contractions of the alæ of the nose. Adenoids had been removed some months before, and the patient had also been circumcised. Glasses gave considerable relief, but the movements did not entirely cease until the patient was brought under the influence of arsenic. The author thinks that in his case the conditions were largely due to the eye conditions, being a manifestation of habit chorea.

The Psychic Treatment of Nervous Diseases from a Practical Standpoint.—C. A. Penrose notes the recent efforts made in some cities to introduce the methods of psychical treatment on a rational basis and to do away with the claptrap of so-called Christian Science. Contrary to the general belief of the laity, psychic treatment has not been neglected by the profession, but under modern conditions of living there is an increase of a certain degenerate type of mind fast spreading over the country. There is a large group of persons who are "mind weary," a condition which is a sort of reaction against the strain and turmoil, the ambition and excessive nerve restlessness of the present day. This class of persons are easily imposed upon. They do not care to think or investigate. They will accept almost any statement rather than take the trouble to deny it or argue it down. They thus become the prey of the imposter. It seems to the author a dangerous procedure to turn even the purely functional neuroses over to untrained men for treatment, even if they can give efficient mental treatment, owing to the impossibility to determine, often, what is organic and what is functional, or how dependent the mental state is on the badly developed or poorly nourished body. The paper is a plea for scientific study along the lines of physical needs and physical development and the scientific treatment of the same.

Prevention of the Nervous and Mental Disorders Incident to School Life.—The main points of the paper by J. H. Pleasants are thus summarized: (1) Children under eight, or, better, ten, should not attend school if country life and parental attention are possible. (2) City children between five and eight should be placed in kindergartens situated in parks or suburbs, where nature study and systematized play and light ungraded objective work in the open air can be carried out. (3) Schools for older children should be gradually removed to the parks or suburbs and equipped with playgrounds and physical directors. (4) Overstudy and competition among the more ambitious pupils should be prevented, and the leveling of the child to the grade avoided. (5) The hygienic condition of the schools should be maintained at the highest efficiency, both for the effect upon the child's health and as educational object lessons. (6) Physical defects (usually remediable) at the basis of many mental and nervous disorders are principally: (a) Malnutrition, to be combated at present largely by the educational influence of the school nurse; (b) eyestrain, if of advanced grade, or if productive of symptoms, to be corrected, and the wearing of glasses made compulsory; (c) adenoids and enlarged tonsils to be removed; in neglected cases the health department should have power to enforce removal; (d) deafness to be prevented by the better control of epidemics and removal of adenoids. (7) Epileptics to be placed in separate schools, or, better, in rural colonies. (8) The condition of many so-called mental deficients improved or cured by correction of physical defects. (9) Truancy and incorrigibility in many cases due to the handicap upon mental work of physical defects. (10) Education of idiots, imbeciles, and the feeble minded, as far as they are capable, in special institutions maintained by the State. (11) The education of children slightly below par mentally in small ungraded classes in the public schools. (12) Substitution of a broad medical supervision over education by a board of physicians and educators rather than mere medical inspection.

Varicose Veins; Their Treatment by Multiple Short Incisions.—C. F. Kivlin discusses the occurrence of varicose veins, their complications, symptoms, diagnosis and the usual methods of mechanical and surgical treatment. He then makes a plea for the method of multiple short incisions, claiming that it does not take so long to do the operation as it does with other operations where the vein is removed, that it is not so apt to become infected, and that if one incision becomes infected it can be dealt with more readily and without infecting the others. There is no scar tissue at the knee joint, thereby causing no pain nor limping while walking. There is practically no blood lost, especially none from the main vein; what little blood is lost is from the skin. Convalescence is much shorter, a week to ten days' time being sufficient for the patients to stay in bed; they should be up to work by the end of two weeks. But if it is a case where it was urgent for them to be back to business, three to five days would be sufficient to stay in the hospital before returning to light work. The convalescence is painless and uneventful. The style of closure is either interrupted or continuous. He believes, however, that the continuous silk suture is the best closure.

Journal of the American Medical Association, January 18, 1908.

Arteriosclerosis.—G. L. Walton and W. E. Paul conclude as follows: While arteriosclerosis is productive of apoplectiform attacks and vertigo, and plays a part in the causation of loss of memory as well as other failures of power in involution, it does not produce headache except as the immediate result of apoplectiform attacks. A number of the patients stated that the headaches from which they had formerly suffered had lessened or disappeared of late years. The comparative immunity from headache was the more notable in view of the fact that signs of renal degeneration were present in thirty-six per cent. of the cases and the blood pressure averaged high. The apoplectiform or claudication attacks are, moreover, not necessarily indicative of serious organic disease, as a case which they report shows, and they are inclined to credit them to cerebral fatigue with temporary suspension of function rather than to actual changes in the vessels. Arteriosclerosis naturally appears in a certain proportion of elderly neurasthenics, but their observations fail to establish its causative influence, and they feel that further investigation of this point is desirable. Renal degeneration is a prominent factor in the cardiac enlargement often present in cases of arteriosclerosis. Arteriosclerosis without cardiac enlargement or renal degeneration is only exceptionally accompanied with a very high blood pressure. If either cardiac enlargement or renal degeneration exists, moderately high blood pressure is the rule; if both are present, very high blood pressure.

Upper Respiratory Obstruction and Oral Deformity.—F. A. Faught reviews the dental literature of the subject, in which he finds a tone of uncertainty and some surprising contradictions of opinion which have led him to formulate a series of questions which were submitted by him to a number of authorities whose replies are analyzed and commented on. The answers bearing on the question of the lateral expansion operation and its effects on upper respiratory obstruction are particularly discussed. The author's general conclusions are that the data are still lacking to put the question of the interrelationships of dental and maxillary deformities and respiratory disturbances on a definite basis, but he believes that in the vast majority of cases dental irregularity is associated with, if not dependent on, upper respiratory obstruction—hence the need of dentists, and particularly orthodontists, being familiar with the forms of respiratory obstruction, their symptoms, diagnosis, and treatment. There should be a careful study of the changes caused by corrective procedures and more accurate methods of observing and recording them. The treatment of dental irregu-

larity should be preceded by examination and treatment of conditions in the nasal chambers and pharynx. The result of the ordinary expansion operation as regards nasal conditions is more dependent on vital tissue in the nasal region than on mere mechanical movement. Operations designed mechanically to increase the respiratory capacity of the nasal passage are practically valueless unless the intermaxillary suture is separated, as shown by the increase of space between the central incisors. It is impossible to relieve stenosis due to adenoids or septal irregularities by expansion methods; these should be attended to by the rhinologist before attempt is made to correct the dental defect. The stimulation of the vitality and renewed growth in the nasal chambers, together with the restoration of normal conditions in adjoining parts are the chief causes of improvement following expansion operations.

Subacute Polymyositis.—B. T. Burley reports three cases, two of them fatal. The infectious nature of the disease is suggested by some of the symptoms, the onset with malaise, the fever, and the often recurring splenic enlargement, and some reported cases even suggest contagion as well as infection. There is, however, no definite proof of either of these elements in its etiology. The pathological findings vary according to the stage of the disorder; the signs of inflammation, swelling, infiltration, transudation, and hemorrhage are seen early, and it is characteristic of the disease that certain muscular bundles and certain fibers of a bundle are unaffected by the process. Later there is a general tendency to degeneration of the muscular fibers and their change into connective tissue. The nerves have been found to be involved in some cases, but this does not appear to be a primary change. The amount of hemorrhage between the muscular bundles is variable; it may be very great, giving rise to the designation, polymyositis hæmorrhagica. The two affections likely to give trouble in the diagnosis are trichinosis and polyneuritis, though phlebitis, periostitis, rheumatism, and pyemic abscess sometimes resemble this condition. From trichinosis it is distinguishable by microscopical examination and by the characteristic eosinophilia of the latter disease. Leucocytosis is also more common in trichinosis and primary gastric and intestinal symptoms and involvement of the muscles of the eye and diaphragm are more characteristic of trichinosis. In polyneuritis there is tenderness along the nerves instead of over the muscles and anesthesias and parasthesias that are absent in polymyositis. The inflammatory edema involving both muscle and subcutaneous tissue and the muscular swelling followed by atrophy point to polymyositis. The reflexes and electric reactions may be mechanically affected in polymyositis, and polyneuritis may coexist. Syphilitic myositis is a rare affection that may be confused with polymyositis, but it is accompanied by evidences of specific infection, usually affects but a few muscles, and has not the splenic tumor nor the exanthem of polymyositis. The prognosis is not regarded as so unfavorable as formerly, since the recognition of the milder cases. General involvement of the muscles and cutaneous tissue with persistent fever make the prognosis graver. Myocardial involvement adds to the danger. The most serious single symptom is involvement of muscles of deglutition. Atrophy of some muscles is common after recovery from long-continued cases. There is no specific treatment. The cases reported, following the classification of Lorenz, would fall under the head of dermatomyositis, but on account of their characteristic insidious onset and slow course, and the general involvement of the muscular system, he prefers for them the title "subacute polymyositis."

Dementia Præcox.—S. E. Jelliffe defines the conception of dementia præcox, which he considers a fairly reasonable entity, as based on the following principal features: 1. The occurrence of the condition, for the most part, in the years about puberty, adolescence, and early manhood, *i.e.* between the ages of 18 and 28. 2. The gradual development of a psychasthenic state deepening into a sense of incapacity which is the beginning of a general process of mental deterioration. 3. Thus a gradual emotional deterioration becomes apparent. This may be an indifference, or emotional stupidity, or may be characterized, as Stransky has so well shown, as an incongruity between the content of ideas and their natural emotional sequence. This incongruity has been compared to an ataxia by Stransky, and there may be more complete dissociation between ideas and their usual emotional association. This emotional adjustment is one of the marked features. 4. Modifications in the so-called intellectual sphere are apparent, involving lucidity of consciousness and leading sometimes to complete confusion; variation in power of attention; some modification of the faculty of orientation, often not marked; delusion development, often on an hallucinatory basis; loss of perceptive power and the development of the sense of unreality, of inadequacy, ideas of influence, of reference, and compulsory ideation. 5. As a consequence of these and other reactions, there results a fairly constant and perhaps distinctive alteration in the character of the individual. Jelliffe believes that the structural defects that later permit the crumbling of the intellectual structure are detectable in many cases before the breaking down has begun. Among the more constant of the characteristic anomalies are affectations or eccentricities of manner; a tendency to seek out striking combinations, neologisms in speech, bizarreness in writing, in artistic production and inapproachability. The finally developed childish, foolish manner so frequently seen as an end product is also perhaps best considered here. 6. Finally, these patients show marked modifications in their general muscular reactions, both in the striped and unstriped muscles. Physical negativisms, stereotypies, affectations of posture and bearing, catalepsies, automatisms, and a host of sympathetic phenomena are here included. Jelliffe points out briefly the different characteristics of the different types, the cases of simple dementia or hebephrenic form, the catatonic and the paranoid groups, and goes at some detail into the psychology of the condition. Most of these patients, he says, are not hopeful cases, but some are worth working for, particularly in the predementia stage. When the diagnosis is patent the opportunities for repair have usually been neglected. He believes in training the eccentric and ego-centric children, who recruit this class of the insane, with special reference to their capacities, combining outdoor pursuits with education and utilizing the petty social conventions that lessen the opportunities for unregulated affective action.

Münchener medizinische Wochenschrift, January 7, 1908.

The Cutaneous Tuberculin Test.—Feer reports the results of the application of von Pirquet's tuberculin inoculation test in 344 children below the age of fifteen years. Of the number 19 per cent. gave a positive reaction, none of them being less than six months old, and only 7 per cent. of the positive cases occurring in children less than twelve months old. Fifty-seven per cent. of the number were between the ages of ten and fifteen years, the increasing proportion of positive results as the subjects increased in age being very strikingly shown. Of 25 cases clinically certain as tuberculosis, 24 gave a positive reaction, the exception being a thirteen month old infant with tuberculous peritonitis, the diagnosis being confirmed at autopsy. He considers that the cutaneous method has the same value as the hypodermic injection of tuberculin, while it possesses many evident advantages over the latter. In dealing with older children and adults many positive results are obtained from individuals ostensibly healthy, that is, having small inactive foci, and the reaction is therefore of little value with them and a negative outcome is of more importance. In young infants, however, the method increases in value the younger the child. The cutaneous inoculation is greatly to be preferred to the conjunctival application of the tuberculin owing to the serious risk of producing corneal ulceration and other complications.

Typhoid Bacilli Carriers in Insane Asylums.—Grimme says that the discovery of the fact that typhoid bacilli carriers are common among the inmates of asylums for the insane has added a new problem to the management of these institutions. It is not true, however, that the insane as such are more likely to be permanent hosts of typhoid organisms than other persons, but the apparent preponderance of this class is to be explained by the fact that it is only in insane asylums that systematic observations with this end in view have so far been carried out. The treatment of the bacilli-carrying inmates is difficult since their isolation, which is desirable from the standpoint of the institution, is entirely at variance with modern ideas on the treatment of the insane, and is likely to result to their serious detriment. Medical treatment directed to the condition has been found of little or no avail and the most promising outlook is that offered by the results obtained in several cases in which the gall bladder has been opened and cleansed. The author reports one more instance of this sort in which a cholecystectomy was done apparently with the result of effecting a complete cessation of the discharge of bacilli, and he commends the operative measures for consideration in cases of this type which are not unsuited for surgical intervention.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

One Hundred and Second Annual Meeting, Held in Albany, January 27, 28, 29, and 30, 1908.

(Special Report to the MEDICAL RECORD)

Monday, January 27—First Day.

HOUSE OF DELEGATES.

THE PRESIDENT, DR. FREDERIC C. CURTIS, OF ALBANY, IN THE CHAIR.

AT the meeting of the House of Delegates, which was held in the Common Council Chamber, City Hall, at 8.30 P. M., the following reports were presented:

Report of the Secretary.—Dr. WISNER R. TOWNSEND presented this report. The membership January 21, 1907, was 5,857; during this year there were 102 deaths, 50 resignations, 7 removals, and 1 expulsion, leaving a membership of 5,697. The new and reinstated members January 21, 1907, to December 31, 1907, were 626, giving a membership at the latter date of 6,323. There were dropped for non-payment of dues, December 31, 1907, 343. The percentage of paid-up membership December 31, 1907, was 94.5 per cent. The membership January 15, 1908, was 6,154. No State society could show better results. The full benefit of the district branch organization to the profession had not yet been reached, because the system was new in this State and not thoroughly understood. There were but fifty-six unregistered physicians in the State, some retired and some in the employ of insurance companies. It would seem desirable that this society should be represented by delegates at the annual meetings of the societies adjoining it. The present plan of issuing credentials to those who apply did not always produce this result, and it was suggested that the President be requested to name delegates to such societies and also permit members who attend the meetings and desire credentials, to have them, as at present was the custom.

Report of the Committee of Legislation.—Dr. ARTHUR G. ROOT presented a brief summary of the legislation affecting medical interests introduced during the session of 1907. Sixty-four bills were introduced, of which number eighteen had become laws. Of these sixty-four, twenty-one were general medical bills; of these, fifteen died in committee, four became laws, and two did not receive the Governor's signature. Three of the sixty-four were bills referring to the gathering and sale of ice from polluted sources. All these died in committee. Eight of the sixty-four bills had to do with the health of factory children and working women and the general hygienic care of the working classes. Two died in committee, and six became laws. Of the seven having reference to tenement house legislation, five died in committee and two were signed by the Governor. Twenty-five related to pharmacy, the sale of drugs, poisons, etc.; of these eighteen died in committee and seven became laws.

Report of the Committee on Public Health.—Dr. JOHN L. HEFFRON said that the State Laboratory at Albany was now making the antitoxin for tetanus and a certain quantity of antitoxin for diphtheria, and said that the committee recommended that these laboratories be extended. The condition in the northern part of the State to-day, where an epidemic of smallpox was raging, was clearly due to a careless vaccination, which had been bred by a general, though mild, opposition of the people to the State law requiring general vaccination. Many useful lives and millions of dollars would be saved if a pure virus was procured and rigid enforcement of the law compelling the vaccination of every child entering school, etc. Tuberculosis still continued to head the list of causes of death. It had been estimated that seven-eighths of the deaths in this State were due to respiratory diseases, together with the diarrheal diseases of children. This awful record was certainly not necessary. They were now ready for a law making it a duty to report all cases of tuberculosis for the successful protection of the victims themselves and of their friends. The committee recommended that the society cooperate with the State Department of Health in the passing and administration of a law for the reporting and registration of all cases of tuberculosis in the State. The State Hospital for Incipient Tuberculosis at Ray Brook had done such good work that the extension of the plan was urged. They recommended the careful study of the plan of campaign carried out in Yonkers. Next to tuberculosis the most prevalent cause of death was pneumonia. The necessity of securing for the people pure water, pure ice, and pure food was emphasized.

Other Reports.—The Committee on Prize Essays reported that no essays had been presented during the past year. The Treasurer, Dr. Alexander Lambert, reported a surplus of $13,849.03 on December 31, 1907. The Counsel reported that there had never been a single dollar by way of verdict secured against any member of the State Society who had asked of the society and received malpractice defense. He reported that there had come to his knowledge two cases in the State, neither of which was defended by the Counsel; one resulted in a verdict of $25,000 against the physician and the other resulted in a verdict of $2,000. The special committee on meetings recommended semi-annual meetings to continue two days each.

Tuesday, January 28—Second Day.

SCIENTIFIC MEETING.

The meeting was called to order by the president in the Common Council Chamber, City Hall. The Rev. J. V. Moldenhower gave the invocation. The reception of delegates from other societies followed.

President's Address.—Dr. FREDERICK C. CURTIS of Albany delivered this address. He said that each annual meeting reflected the manifestation of thought and estimates of value in the varied phases of professional life. Every page in the world's history taught the value of organization. This Medical Society of the State of New York had one definite purpose in its organization over a century ago, viz., the association of all reputable physicians, and the exclusion of the unworthy. It had little use for trades union methods. The history of all the learned professions imperiously proved that no one profession ever became reputable or of extensive use to mankind unless under proper restraint, restraint of the body and its members. This year on the statute books was the medical practice law, the culmination of what the society had endeavored to effect for twenty-five years. The organization was wide open for the young men, and he hoped that all reputable practitioners in the State would be induced to come in. He would simply draw a line against the unworthy. His purpose was chiefly to indicate how admirably the society fitted the work by an ideal organization and composition. This involved upon it an obligation of service. He thought, however, that most medical men were inclined to forget their obligation to the public. People, as a rule, were apt to obstruct work for their safety rather than to help it. In many instances the Department of Health had been pushed aside for what might bring money into service. History bore witness of the material worth of sanitation. Diphtheria had been reduced to one-half in its mortality, and diarrhea and summer complaint of infants had been equally diminished. The infection in consumption had been recognized. The value of pure water and milk had been told. But all this had been a labor of love.

The average physician who was not directly connected with the work failed to give support to the work that he should, and Dr. Curtis told how he could give help in many ways. A subject peculiarly fitted for discussion by the organization was the alcohol question. There was a tremendous use of alcohol which filled hospitals, asylums, epileptic colonies, and prisons, telling of its destructiveness. In many States alcohol was now excluded, and he believed that the Medical Society of the State of New York should find some definite way to leadership against it. The importance of the educational life of the growing child was emphasized. The widespread existence of ophthalmia neonatorum showed the responsibility there was in the care of infants, and so long as it continued to be the leading cause of blindness, the society should take such steps as were necessary to see that this dire evil might be lessened. The society should know the obligations that lay upon it, and there should be shown a faithfulness in its attitude toward them.

Nihilism and Drugs.—Dr. Abraham Jacobi of New York delivered an address on this subject, and in a very facetious manner, causing much laughter and applause. A physician should be judged, he said, by the extent of his knowledge and not so much by his cures. So long as medicine was an art, it would never become a science. So long as the physician was successful, he would not be scientific. So long ago as 1860 Oliver Wendell Holmes said that if one threw out opium and a few other specifics, and threw the rest of the agents making up the pharmacopeia into the sea, it would be better for the people, but bad for the fishes. More harm than good had been done by medication, was what Sir Astley Cooper said. After all it was not of the slightest interest whether one-half or three-quarters of the lungs was hepatized; what the people really wanted was something to make them better. The year 1907 was disquieting because of tidings from Dr. Osler; the telegraph had reported that he had said to his students in London: "Be skeptical of the pharmacopeia; he was the best doctor who knew the worthlessness of medicines; study the man and the woman" This message, or a similar one, was sent out over the world. He was the *enfant terrible*, was what the *Evening Post* of New York said of Dr. Osler. What Dr. Osler probably and really meant was, first, be critical and frank; second, he was the best doctor who knew the worth of medicines; and third, study your fellow man and fellow women and learn how best you can serve them. Therapy meant service. Dr. Jacobi said he wished Dr. Osler had said that. We had been told that by combining medicines we might cloud observation; that that was what physicians had been doing so long, and that it was not right. It should be remembered, however, that they were treating disease and not men and women, and there were those who did not care to wait for the action of one drug given for the relief of one symptom to wear off before giving another for another symptom, when, by combining the two, the results wanted could be obtained in a shorter time than if they were administered separately. It was about as wise as restricting the physical treatment to one single method. Why prescribe one and proscribe the rest? Dr. Jacobi had much to say regarding the expectant treatment. In 1836 Dixon said that the tendency of all diseases was toward death Dr. Jacobi said that the expectant treatment had been the cause of many deaths; that often death resulted when proper treatment might have saved the patients. Typhoid fever, for instance, if left to itself, might prove fatal, and so might whooping cough, and many other diseases. The expectant treatment often was a compound of ignorance and indolence, often it was malpractice in cases which might have been saved by proper treatment. The expectant treatment was simply a sin of omission which frequently arose to the dignity of a crime. His meaning was illustrated by the citation of interesting cases. Expectancy meant loss of time and opportunity. In regard to drugs and their doses, the latter were dependent upon many factors, such as age, sex, locality of application, the amount of blood circulating in the vessels, the presence or absence of sepsis, etc. He spoke of a child with enteritis, one year old, who would take from 1/30 to 1/40 grain of opium. He said he had never seen a case of opium poisoning occur in his practice in such cases, and he believed the dangers accompanying the use of opium in young children had been much overestimated. He said that one grain a day of atropine given an adult would cause dilated pupils, dry throat, etc., while a child of four years could take as much as one-half a grain in enuresis with no such effect. He then referred to many agents and drugs which were of great value; many had been used for a long time, such as the poppy, mercury, quinine, male fern, etc. Seroorganotherapy had not come up to expectations. It was interesting to know that most of the bad and the good medicines came to us from Germany. In 1897 a South Carolina colleague had employed methylene blue in inoperable cancer, and Dr. Jacobi said he wished to acknowledge this doctor's claim of priority. With regard to the drug therapy of tuberculosis, for nearly twenty years he had used guaiacol in at least five thousand cases and he did not believe that any institution should leave out this agent in the treatment of this disease.

Clinical Observations on Vaccines.—Dr. Joshua M. Van Cott of Brooklyn reported ten cases in which opsonic therapy was employed, and said that in the majority of these cases the patients no doubt would have died had the vaccines not been administered. It was certainly worth while to pursue this further, and he hoped that the vaccines could be manufactured so that these patients could be carried through their diseases.

Report of Some Cases Treated by Vaccines.—Dr. Algernon T. Bristow of Brooklyn said that the organism had two ways of resistance; one, the specific action of the blood serum; second, phagocytosis. But it was more upon the latter that defense depended. Wright himself had confirmed the statement that vaccines were of no use when the organisms were found in the blood. At the same time it was our duty to conduct further investigations which might give more hopeful methods of treatment. He said that we should not be led astray by any failures or successes. What was wanted was evidence. He wished to report a few cases of interest. Among these was one case of streptococcic infection in which the organism was not found in the blood. In another a streptococcal form was found in the blood in a case of malignant endocarditis.

Case I.—This patient was a woman, fifty-eight years old, who, at intervals of one week, for three weeks, had rigors, chilliness, high temperature, and headaches. These symptoms would last one or two days and she would then apparently recover. Between her second and third attacks she went about her social duties. On March 11 tenderness was noted on the left side of the neck, and enlarged glands. This tenderness increased until she had positive pain. The temperature varied from 100° to 103°. Twenty-six days after the initial attack Dr. Bristow saw her. She then had a temperature of 102° and there was a circumscribed swelling in the submaxillary triangle, moderately painful on pressure. It was decided to wait awhile before

making an incision. There were 15,000 leucocytes and 78.8 per cent. polymorphonuclears. From March 17 to 21 the temperature was irregular, and ranged from 100° to 102°. The swelling became more diffused and extended towards the clavicle. The number of leucocytes diminished to 10,000 and the polymorphonuclears were 75 per cent. There was no fluctuation. The pain in the neck diminished. He again saw her on the 23d, when the tumefaction extended to the clavicle and operation was decided upon. Just before operation the blood count was 11,000 leucocytes and polymorphonuclears 83 per cent. Deep in the cervical fascia was an abscess cavity from which pus was evacuated and a tube introduced. At the time of operation the temperature was 100.4°. On the 26th the pulse became intermittent and cardiac stimulants were given. Pain appeared in the left leg, but there were no evidences of a phlebitis; there was tenderness over the left condyle. The second sound became accentuated, and there appeared a soft blowing murmur. On the 29th the patient seemed to be improving, but there was pain in the right knee, the right wrist, fingers of the right hand, and the right side of the shoulder joint. On the 28th she went into convulsions; after regaining consciousness she felt weak. Two organisms were found in the pus, one a streptococcus and another which resembled very closely the bacillus of diphtheria. Carbonate of guaiacol was administered. Dr. Potter was communicated with with the view of using the vaccines. The patient was very ill. They determined not to wait to obtain an organism from her, but to use a stock vaccine. On April 2 they gave five million. The next day the temperature was 104° and there occurred a second convulsive seizure. On April 10 ten million were given. The patient steadily improved from this time and soon regained her good health.

Case II.—This patient was twenty-one years old. The organism was found in the blood. She had rheumatic manifestation in childhood, and gave a history of rheumatism. With this diagnosis she came in. After three weeks treatment she became unconscious and her condition was very bad. Examination of the heart revealed a mitral murmur. She complained of intense headaches and contraction of the neck muscles. The joints were not swollen. There were no albumin, casts, or other abnormal ingredients in the urine. Antirheumatic remedies had been given. Six days after admission the left elbow became swollen. She did not improve. A blood culture revealed the presence of the *Streptococcus longus*. She received two or three doses of antistreptococcic serum, but without effect. They then determined to use the bacterial vaccines. On June 1 the patient again became unconscious and five million of the same culture as in the first case were injected into the thigh. On June 3 ten million more were injected and later five million more. The patient went on then to an uncomplicated recovery.

Case III.—This patient was a trained nurse who, from August, 1905, to June, 1907, was troubled by crops of furuncles. They were all over the body. The *Streptococcus pyogenes aureus* was isolated. The bacterial vaccines were administered in June, 1907. She remained free of furuncles until the following October, when she had a single boil which cleared up after the injection of more vaccines.

Case IV.—This was a boy, eighteen years old, who had an arthritis of the right knee of gonorrheal origin. A small incision had been made and the joint washed out with saline solution. The joint was much swollen and painful, and the case seemed very unpromising. A dose of seventy-five million was injected and one week later the case suddenly improved.

Dr. Bristow said that no definite conclusions could be drawn from such a small number of cases, but the results appeared to be encouraging.

Description of Wright's Methods.—Dr. William H. Woglom of Brooklyn told of the technique used to determine the opsonic index, illustrating his remarks by drawings. In order to make this estimation, three elements had to be considered: the serum, the washed leucocytes, and the organism against which they desired to obtain the index. The serum he divided into two classes: first, of the patient in question, and, second, the serum of a healthy individual or individuals to serve as a standard. He then told how one obtained the washed leucocytes, using a tube, a solution of sodium citrate, and blood, and centrifuging until the leucocytes were at the bottom of the tube. This was repeated and finally the fluid was pipetted off. The serum was collected in glass capsules. He told then of how the bacterial emulsion was made. The thickness of this emulsion must be judged of by experience. Having these three elements one then could go on with the estimation of the opsonic index.

The Value of the Opsonic Index in Controlling the Use of Vaccines.—Dr. William H. Park of New York said that Wright deserved credit for two things in particular in the opsonic work: first, he induced physicians to make more frequent use of opsonins and showed possibilities not before dreamed of. He thought it would take years before we knew of how much value the opsonic index was as an indication in the treatment of disease. Wright was an optimist. After Wright had left this country he left here one of his trained assistants to show his methods and to follow out cases that were treated. At that time they were beginning their laboratory experiments and knew but little about the technique. They found that when they made the indices with the aid of this assistant he would have a high and they a low index. But it should be remembered that this assistant was working in a strange country and in a strange laboratory. For a long time many of them worked along with different ideas as to accuracy. Dr. Park then spoke of a few of the difficulties encountered, such as individual peculiarities. Different individuals in good condition gave from 10 to 15 per cent. or more variations. Therefore, the same person must count the control blood as well as the blood to be tested. Another greater difficulty was the irregularity with which the leucocytes took up the bacilli. Another difficulty was the technique; one must have proper cultures to get the opsonic index. Different cultures would give wide variations. To get a culture from an individual was no easy matter. Another difficulty was in the measurement not being absolutely true. Eating, drinking, taking cold, etc., raised or lowered the index. There was great irregularity in disease, a very marked variation. In tuberculosis it might be one-half under or one over normal to-day, and one over to-morrow. One should not forget that there were other protective substances in the blood. To show the extent of variations in the opsonic index samples of blood were sent to ten of the best laboratories in the East, in Boston, Baltimore, Albany, and New York City. Reports from all these laboratories, ten in number, showed marked variations. Last summer Dr. Potter and Dr. Park visited Sir A. E. Wright in London and they were struck by his enthusiasm and the results obtained by him. Many of the patients no doubt did better than if they had not received the vaccines. Yet the opsonic index was not absolutely necessary in controlling the use of the vaccines.

Dr. Delancey Rochester of Buffalo and Dr. Boswell of Rochester discussed the papers.

Dr. Park and Dr. Van Cott closed the discussion.

The Importance of Examining Individuals Exposed to Tuberculosis.—Dr. JOHN H. PRYOR of Buffalo read this paper. He said there were 14,000 deaths each year from tuberculosis, one-tenth to one-eleventh of the total number of deaths, and that from year to year there were slight variations; although the death rate might diminish, the actual morbidity from this disease was but slightly decreased. The influence of special measures for limiting its spread was a point for controversy. He had asked 100 patients if they had ever received proper instruction as to what should be done in the way of prevention of the infection of others, etc., and they all had answered no. This did not apply to New York City. There were now about 50,000 on their march to the grave in order to keep up the annual death rate from tuberculosis at 14,000 deaths. Undoubtedly registration was the first step in the campaign. But the majority of the cases reported were the advanced ones and had been dangerous for a long time. The chances of infection, however, had been relatively reduced. The rooms or house might be disinfected after a death from this disease. The whole system, as it existed to-day, was a diplomatic game between the doctors and the health authorities. Dr. Pryor advised State control and more uniformity in execution and obedience. Also an adequate knowledge on the part of the health authorities before appointment; they should be specially trained. Again there should be the introduction of some scheme for the detection of tuberculosis at the earliest possible moment when lives might be saved. No consumptive should be allowed to reach a stage where he could communicate the disease to another without having been properly instructed. The class of cases they were looking for was the one that had been exposed to infection. The detection of the early cases made prevention possible. One consumptive should lead one to another. The principal places to search were the houses and the workshops. In examining suspected cases success depended upon recognizing the disease; a bare chest examination should always be inisted upon. Those exposed to infection should be kept under observation for a long time. The second victim in a home was not usually detected until nearly one year after a death had occurred there. An effort should be made to discern evidences of the disease before symptoms appeared. Very often it was the occurrence of hemoptysis that sent the patient to the physician. Exposed individuals should be instructed as to what symptoms might appear. Some families were very susceptible, and he had seen one family in which eleven of thirteen died of pulmonary tuberculosis, the father and mother having enjoyed good health. He called attention to the three groups that should be recognized in children, the glandular, the tracheobronchial, and the pulmonary. The instructions should include the question, have others in the house been examined? It was a strange but true thing that the average practitioner was not able to recognize the disease early; he had not been taught how to diagnose in the earliest stages that most fatal of diseases, tuberculosis. Truly incipient tuberculosis had been revealed by examining those known to have been exposed by contact with advanced cases, and physical signs presented before the patients complained of subjective symptoms. The invasion was slow and repeated examinations might be necessary. The physician's duty was not fulfilled if those exposed to tuberculosis were neglected. There was false dependence upon the appearance of the bacilli. He gave illustrative cases and reported an endemic outbreak of pulmonary tuberculosis showing remarkable evidences of communicability. There were nineteen nurses and of these nine were found to be the subjects of pulmonary tuberculosis. Months would probably elapse before fuller information would be known.

Dr. GOODALL and Dr. ROCHESTER of Buffalo discussed the paper.

Dr. PRYOR closed the discussion.

The Treatment and Prognosis of Suppurative Cystitis.—Dr. VICTOR C. PEDERSEN of New York read this paper. Because of the time allowed him, he said he would consider only chronic cystitis. Chronic inflammations depended upon the character of the cause and the degree of the effect. If the cause was removed a total recovery might take place if the membrane had not been deeply damaged. The cystoscope would reveal the extent of the impaired membrane. In chronic cystitis many of the causes might be removed by dividing strictures, or dilating them, calculi might be removed from the bladder, hypertrophy of the prostate reduced, or the gland removed, etc. Cases of chronic cystitis could not be cured when associated with disease of the spinal cord, or injuries there, which resulted in a trophic cystitis; neither could tuberculous or cancerous cystitis be cured. The measures adopted were local and constitutional. Good hygienic surroundings, exercise, sleep, diet, drinks, stimulants, hydrochloric acid and pepsin, or pancreatin, were all of value. The bowels required washing. Turkish baths were good. When there was any cachexia or diathesis, it should be corrected. All diseases, especially of the heart, should be managed. When the cystitis was practically well change of climate should not be forgotten. Digestive fatigue, nervous fatigue, physical fatigue, and other fatigues should be guarded against. The local effect of the constitutional treatment was the same for chronic as for acute cystitis. He favored diluting, acidifying and antisepticizing the urine with water and medication. If there were no casts in the urine urotopin could be used with benefit. Sandalwood, copaiba, and oil of gaultheria, alone or combined, was of value. All bladder stimulants were to be avoided. Irrigations, instillations, and drainage by catheter, or perineal or suprapubic section had their place. Irrigating the bladder aimed at aiding nature in eliminating the mucus, pus, and debris; it combated infection and stimulated and healed the inflamed mucosa. Forcible distention of the bladder should not be done. The use of a hand syringe was recommended by which the pressure could be more easily determined. Normal saline solution, sodium carbonate solutions, or even sterile water irrigations might be used until the fluid that appeared returned clear as inspected in the test glass. The posture of the patient should be such as to get a free outflow of urine. The temperature of the fluid used might be raised with advantage. The amount injected should be measured. No pain should be given the patient. A bladder with a large amount of residual urine might hold from eight to ten ounces of fluid without distention. One should always run in just enough to unfold the crevices in the bladder. The irrigation combated decomposition and fermentation. In chronic cystitis the strength of the solution should be increased gradually, and a small amount of the solution should be left in, about one-quarter or one-half the usual capacity. These irrigations also stimulated and healed the diseased mucosa. The repetition of the irrigations depended upon the return of the symptoms. One irrigation a day usually sufficed, and then the intervals should be increased to two a week or every third day. If the combined results of local and constitutional measures were of no avail, then the operative work was to be considered. He emphasized the importance of the cystoscopic examination in all cases before giving a prognosis.

The Consequences of the Pathological Changes in Appendical Peritonitis.—Dr. E. MACD. STANTON of

Schenectady said that in appendical peritonitis one had to do with a complex sequence of changes in which the essential characteristics of the pathological picture varied from day to day. The essential features of this sequence of pathological findings were described as observed in a large series of operative cases studied with special reference to the duration of the disease. The sequence of changes was shown under certain conditions to be uniform and to have important bearing upon formulation of proper plans of treatment. One hundred and sixty-two acute cases and 131 interval and chronic cases were observed in Chicago, 41 cases were observed in Schenectady, while 485 cases were observed in the Albany Hospital, making 819 in all which were studied with reference to the pathological changes. He closed his paper by stating that the claim of those who advocated conservative treatment in appendicitis was founded upon a more definite pathological basis than was generally recognized by the profession at large.

Dr. Ochsner of Chicago said that the observations of Dr. Stanton were so accurate and complete that he was sure that from now on his paper would stand as a basis for professional opinion in regard to the pathology of acute appendicitis. He said that it was known to most of those present that eight years ago he brought this out and was looked upon as a heretic, the proposition being that the distribution of the infection and consequent mortality in acute appendicitis depended not so much upon the disease itself as they did upon the disturbance caused by the peristaltic action of the small intestines. He had made the observation that in acute appendicitis in which the infection had already extended beyond the appendix itself, it was possible to limit the distribution and cause it to become localized and circumscribed provided the peristaltic action was inhibited. He advised removing from the stomach anything which might cause peristalsis and keeping the stomach absolutely empty. If regurgitation occurred from the intestines, wash out the stomach. He found too that when patients were examined once a day they had one exacerbation; if twice a day, two, etc. If no examination, no exacerbation. He believed that the claim to superiority of this form of treatment in cases of acute perforating or gangrenous appendicitis in which the infection had already extended beyond the appendix, had been conclusively demonstrated.

Dr. Willis G. Macdonald of Albany said he did not agree with the conclusions of the two gentlemen.

Dr. John C. Monro of Boston commended the paper read very highly and in support of the claims, said that similar pathological changes had been identified in other parts of the body; for instance, in osteomyelitis. The work of Dr. Stanton was placed on a solid and scientific basis. The treatment as advocated by Dr. Oschner he had used.

Dr. Skinner of Geneva said that the non-operative treatment of appendicitis was in accordance with his own views.

Dr. Lake of Towanda recalled his own experience of thirty years ago when he began to follow the teachings of Dr. Alonzo Clark. In those days appendicitis was unknown and yet the mortality was low.

Dr. L. Duncan Bulkley of New York said that fifty years ago he had what was known as typhlitis, but which he later knew to be appendicitis. He was treated by Dr. Alonzo Clark and was kept on opium for six weeks, taking as high as two drams of laudanum every two hours. Under that treatment the infection was localized and at last there occurred a sudden gush of pus and detritus from the bladder, the abscess having ruptured into it.

Dr. Vander Veer of Albany said that just forty-two years ago Dr. Alonzo Clark had stood in a building that occupied the same spot as the present one and told of his treatment. To-day Dr. Ochsner told what was practically the same.

Dr. Stranahan of Rome bore testimony to the good effects of following out the treatment advised by Dr. Ochsner. He had treated 120 cases and with no mortality.

Dr. Stanton closed the discussion.

Diffuse Peritonitis in Women.—Dr. Ellice McDonald of New York City reported fifty cases, with autopsies, of diffuse peritonitis in women. Forty-one cases were studied bacteriologically. The various bacterial causes of diffuse peritonitis were discussed, and the peculiar phases of diffuse peritonitis from pelvic causes and from association with pregnancy, as essential to women, were considered. Suggestions as to treatment were made. Of these fifty cases infection was the result of extension from an ulcer of the bowel in 42 per cent.; from appendicitis in 4 per cent.; following a perforated gastric ulcer in 2 per cent.; following appendicitis in 16 per cent. Apart from pregnancy, pelvic conditions gave rise to 26 per cent. The causes associated with pregnancy caused 30 per cent. of the cases of diffuse peritonitis. Among the infections were the following: The streptococci in 18 cases; the colon in 13; the *Staphylococcus aureus* in 6; the pyocyaneus in 2; the gonococcus in 3; the pneumococcus in 3; encapsulatus aërogenes in 1; tuberculosis in 4 cases. This showed that there was a small proportion of cases in women of diffuse peritonitis due to appendicitis as compared with the high percentage in men.

Exhibition of Bier's Congestive Hyperemia Apparatus.—Dr. James N. Vander Veer of Albany showed the various appliances used in this method of treatment, including Dr. Rudolf Klapp's orthopedic treatment for the relief of ankylosis of the extremities. He also presented a patient with an extensive phlegmon of the neck.

SECTION ON PUBLIC HEALTH.

Tuberculosis in Children.—Dr. Charles G. Kerley of New York read this paper. He said that two features relating to tuberculosis in children had impressed him strongly in out-patient, hospital, and private work. First, the marked resistance which children showed to tuberculous infection, particularly after the fourth year; and, second, the readily traceable source of the infection in a great many cases. He referred to the two chief avenues of entrance into the body, namely, the respiratory and the digestive tracts. In a review of the literature which had appeared during the past few years, one was impressed most by the contradictory opinions expressed as to these avenues of infection. Clinicians, as a rule, favored the respiratory tract as the most important avenue of infection, while many bacteriological and laboratory workers believed that infection through the digestive system, particularly by means of infected milk, was the most frequent one. In the records of a great many cases of tuberculosis in children which had come under his observation, he had been able to trace apparent direct infection by means of inspiration; and the intimate association of the tuberculous child with a tuberculous adult was the rule and not the exception. Dr. Harlow Brooks had recently made some very instructive observations relating to tuberculous infection in monkeys at the New York Zoological Gardens. In these experiments he believed he had shown beyond question by respiratory inoculations that the infection among these animals is transmitted by the respiratory tract, and when measures obviating this means were taken no new cases arose. Not one case had appeared in which it seemed possible that the infection had taken place through the digestive tract. These experiments and observations bore very directly on the question of the route of infection in children, since the type of disease seen in the monkeys and even the organism present were apparently identical with those in children. With these monkeys we knew that the food could not have been infected,

since animals not subjected to respiratory infection in no case developed the disease. Dr. Kerley said that the fact that inspiration of tubercle bacilli was by far the most frequent cause of tuberculosis was further shown by the location and character of the lesion, as proven by autopsy records. In his own cases bronchial gland and lung involvement were present, showing signs that here was the original site of the infection in 34 out of 35 autopsies; and according to Northrup, the intestine was primarily involved in less than two per cent. Northrup was further quoted as authority for the statement that among thirteen children dying from different acute diseases, such as scarlet fever, pneumonia, etc., tuberculous nodules were found in the bronchial glands without tuberculosis elsewhere. Dr. Kerley believed that while infection from milk was possible, it was certainly very infrequent. In regard to infection by means of milk, Vallée, Ravenell, and others introducing the bacillus into the stomach through a tube claimed to have proved that in animals the tubercle bacillus could pass through the intestinal mucosa to the bronchial lymph nodes, and then produce the first macroscopical evidence of the infection. That this might occur in the human remained unproven. He quoted Behring as authority for the claim that practically all tuberculosis infections in man had a bovine origin, and Behring had even gone so far as to announce that not a single case of human infection had been proved. Behring held that the bovine tubercle bacillus was more virulent for man than the human tubercle bacillus. The speaker held, however, that in spite of views to the contrary, up to the present time there was less than thirty proven cases of bovine tuberculosis in man, although a recent case had been reported by Albert Hess in the January *Archives of Pediatrics*. In refutation of Behring's statement the doctor quoted Speck in the *Zeitschrift für Hygiene*, in which he stated that in an investigation of the cases in sanatoria for the tuberculous 73 per cent. of the patients had been breast-fed and 27 per cent. had received cow's milk. Carter had stated in the MEDICAL RECORD that the mortality from tuberculosis in Havana was 21 per cent., and that raw cow's milk was never used there. Heyman had asserted in the *Zeitschrift für Hygiene* that in Greenland infants were almost exclusively breast fed, yet tuberculosis was so prevalent that it was easier to name those who were free from than those who had it. Shiga claimed that bovine tuberculosis was unknown until thirty years ago, but that the human disease had been widely disseminated in Japan for centuries in spite of the fact that up to a few decades ago children, for religious reasons, had been nursed or wet-nursed only. The speaker's opinion was that the use of milk added but little to the mortality from tuberculosis.

What the Rigid Inspection of Milk Is Doing for New York City.—WILLIAM E. BURTON of New York, in charge of Dairy Inspection, Department of Health, read this paper. He said the milk supply of New York City was obtained from portions of Vermont, Massachusetts, Connecticut, New York, New Jersey, and Pennsylvania, it being brought into the city over ten different railroads. The nearest point from which milk was shipped was 48 miles, and the farthest point 415 miles distant. Trains arrived in New York between 9:30 P.M. and midnight. Milk intended for sale in grocery and dairy stores was removed from the station in the early morning and delivered immediately throughout the city; bottled milk was hauled to distributing stations in large wagons. New York City, with its population of 4 1-2 millions, used about 1 3-4 million quarts daily. One-third was shipped in bottles and an additional 15 per cent. to 20 per cent. was bottled in the city, which made the total delivered to customers in bottles about 50 per cent. Prior to 1904 the efforts of the milk inspectors had been directed almost entirely towards procuring a supply of milk which was chemically pure. Inspections had been made at times of local producers, but no systematic method was followed. In the fall of 1904 two inspectors were detailed to inspect all places where milk was handled and to report all abuses found. On June 1, 1906, the systematic work of dairy inspection had been commenced, and a corps of inspectors for country work had been created. Regulations were adopted by the Board of Health covering care of cows, care of stable, water supply, milkers, and utensils. Cattle must be kept clean, long hairs likely to shed or drop dirt during milking process must be clipped; all cattle must be examined by a veterinarian and the report filed with the department. Stables must be well lighted and cleaned; floors tight and properly drained; manure to be removed daily; walls constructed so as to prevent dust and dirt falling to the floor or into the milk; whitewashing once a year was required; pure water for washing utensils was insisted upon; the milk house was to be separated from the stable and dwelling house. Regulations requiring straining and protection from dust and dirt were insisted upon. No farmer was allowed in any manner to adulterate milk or to furnish the New York market any milk which had been drawn from diseased cows. If conditions were unsatisfactory the dairyman was given reasonable time to make necessary improvements; if bad, the time was shortened. If no improvement was made the product of that dairy was refused entrance to the New York market. On March 13, 1907, resolutions had been adopted by the Board of Health requiring creameries to furnish to the department a report stating the existence or non-existence of typhoid fever, tuberculosis, scarlet fever, diphtheria, dysentery, or any other infectious disease in the households of persons employed in collecting or handling its milk. Considerable opposition had been met and it was questionable whether it could be thoroughly enforced without a corps of medical inspectors to control this branch of the work.

Can Tuberculosis Be Eliminated from Cattle?—Dr. VERANUS A. MOORE of Cornell University read this paper. Bovine tuberculosis was a widespread disease. Its extent and rapid increase in various countries had during recent years caused some alarm, both because of its effect in reducing the general food supply and its menace to human life. Its increase in swine and cattle had caused much concern among the large packers and already there were districts from which pork and beef animals were not, because of its prevalence, willingly purchased. As bovine tuberculosis was a specific infectious disease, Professor Moore said the methods for its elimination were based on the recognized principles of segregating the diseased individuals and the protection of the uninfected. The question of what use could be made of the infected animals was an important economic one in itself, but the first problem was their detection and removal from the herds. The speaker mentioned three ways of utilizing the infected animals, namely: (1) Total destruction, except for fertilizer purposes; (2) slaughter for beef under proper inspection; and (3) the separation of infected individuals that appeared to be well and keeping them for breeding purposes.

The following were the speaker's conclusions: (1) Protect the healthy herds by keeping all infected animals from entering them. (2) Properly eliminate all animals exhibiting tuberculous udders or evidence of generalized tuberculosis. (3) As quickly as possible test with tuberculin all animals in the suspicious herds

and segregate the reacting cows. Retest, at frequent intervals, until every infected animal is found and removed. (4) Dispose of the reacting animals by one of the following methods: (a) Destruction, (b) slaughter for beef under proper inspection, (c) isolation for breeding purposes after the Bang method. (5) Never return to the sound herd animals that have reacted to tuberculin, although they cease to react and appear to be perfectly well. (6) Change the practice of maintaining a milking herd by buying in fresh cows and selling the dry ones, to keeping more of the cows during the dry period and raising more calves. (7) Cattle should not be purchased for dairy purposes unless they pass the tuberculin test. All new animals should be watched and tested.

Dr. Rochester asked whether any experiments had been made as to the possibility of the hay bacillus, which resembled in some respects the tuberculous bacillus, being a possible source of tuberculosis.

Dr. Topman of Syracuse cited an instance which had come to his knowledge which showed clearly the unprofitableness to the farmer in keeping tuberculous cattle. It was accidentally discovered that tuberculosis existed in one of the herds supplying the city of Syracuse, and out of a total of 28 there were 25 tuberculin-reacting animals. After the 25 had been disposed of the farmer went into a neighboring county and bought ten cows, and from the ten cows he actually produced more milk than he had formerly from the 28. Dr. Topman thought that if this truth could be properly impressed upon the farmers of the State, and if they could be made to realize that it was actually a losing game for them to harbor tuberculous cattle, it would carry great weight in securing the farmers' cooperation.

Dr. Schoonmaker of Clifton Springs desired to know how frequently a herd of, say, 100 cattle ought to be examined so as to be reasonably sure that the herd is safe.

Dr. Peck of Utica asked what disposition of the milk the reader of the paper proposed to make from the segregated cattle which had reacted to the tuberculin test. He had been informed that about 40 per cent. of the cattle of the State had bovine tuberculosis, and if that was true there was an important commercial question involved, for if we did away with that percentage of the cattle in the State we should immediately be confronted with a milk famine. He did not wish to be understood as arguing for the use of milk from infected herds, but he thought that a very serious economic question was involved.

Dr. Moak was of opinion that infection often took place through the intestinal tract, and recited personal experiences which confirmed that belief.

Dr. Moore responded to the questions asked very briefly. He said that there was opened a great field for research, that we were in a state of evolution, and that he did not think it worth while to discuss the questions at length at the present time.

Milk Production, Old and New.—Dr. L. Emmett Holt of New York City delivered a lantern slide lecture with this title. In 1829, he said, when the city had a population of only 300,000, there were no less than 1,100 whiskey distilleries in New York City. In order to utilize the by-products of the distilleries vast dairy herds as well as piggeries were assembled near them to consume the "slop." The cows were kept huddled together in close, insufficiently lighted, badly ventilated quarters, and were given about one barrel of the "slop" each day per cow, and this was the only food they were supplied with. The men who were employed to milk these cows were described as tramps and vagabonds who worked in payment for a night's lodging. It was from this source that the city of New York in those days received 6-7 of its milk supply. At the present day the milk which was shipped to New York from long distances was of the best quality, for the reason that that produced nearer by was frequently insufficiently iced. In 1893 the first campaign was organized, and from that time there had been a constantly increasing interest taken in the number of bacteria that milk contained, as that was considered the best criterion of cleanliness. The question of whether or not we should have pure milk was merely a question of whether we were willing to pay the price. Milk could be produced just as pure as it was profitable to make it. At the present time the most reliable figures showed that the cleanest milk cost 14 cents per quart to produce. Of course, it was possible to have a milk which was practically sterile, but whether that was really desirable at the present time was a question. In regard to the question of whether milk should be pasteurized, the speaker did not think it desirable to make it a requirement, for the reason that pasteurized milk would not sour, and yet at the same time might be exceedingly fond. It certainly would afford an opportunity to dealers to dispose of milk which otherwise would be unsalable.

(To be continued.)

AMERICAN ACADEMY OF MEDICINE.

Special Conversational Meeting Held at Pittsburg, January 2 and 3, 1908.

The President, Dr. Thomas D. Davis of Pittsburg, in the Chair.

The Purpose of the Conference.—Dr. Charles McIntire of Easton said that the Academy was not on a quest for a course of minimum requirements, nor for a concession course to reduce eight years to seven, but to determine the educational process most likely to produce at once an educated man and a student prepared to become a skilled physician; and to adjust the baccalaureate course and that leading to the doctorate, so that everything would tell and no time be lost. It was realized that the problem was a difficult one and not to be solved at the present meeting. It was thought that commendable progress would be made should it be possible to frame a series of conclusions to be published as tentative conclusions to be at some future time remolded into workable shape. A committee for this purpose was subsequently appointed.

Criticisms of the Present Medical Curriculum.—Dr. Henry Beates, Jr., of Philadelphia, said that the present medical curriculum was a complex made up of courses of study for the medical degree no two of which were alike, either in value or merit. This criticism referred directly to the demonstrated variation in the number of sciences and branches controlling the curriculum of each institution; to the extent of the study demanded for the respective subjects; to the time required for work in each; to the relation and importance given to branch with branch, and, contemplated from the viewpoint of degrees of intrinsic value; also to equipment and duration of the sessions, as well as to the educational qualifications of the students. Excerpts were taken from the report of the Committee on Curriculum of the National Confederation of State Medical Examining and Licensing Boards showing a wide variation in time devoted to the study of the various branches in the medical school. For example, the time devoted to the study of orthopedic surgery varied from 780 hours in one medical school to 13 in another; obstetrics from 460 to 52; general surgery from 2,221 to 78; pathology, from 646 to 48. The time devoted to physiology and chemistry ranged respectively from 750 hours to 56, and from 756 to 78. Dr. Beates believed

that the present medical curriculum should not permit of divided examinations, whereby, at the end of two years, the fundamentals might be eliminated. He urgently insisted that the fundamentals should be perpetuated throughout the full four years, not in the manner of the first two years, but as applied fundamental principles. Another criticism was the disregard of the necessity for co-ordination in the teaching of the respective sciences.

The Essentials of a Medical Education.—Dr. Murray Galt Motter, of Washington, Secretary of the National Confederation of State Medical Examining and Licensing Boards, outlined the essentials of a medical education as:

1. An adequate preliminary training.

2. A medical curriculum based upon sound pedagogic principles, well balanced and closely correlated throughout; a simplified course in which the quality of the work should have more weight than mere quantity.

3. The more careful selection and training of medical teachers and a greater degree of co-operation between them.

4. The subordination of the specialties to the major branches with which they are logically connected, the refinements of special practice being relegated to the post-graduate course.

5. The substitution, in so far as possible, of practical for oral and written examinations, with the preparation and defense of a thesis as a requirement for graduation.

6. Quoting from the chairman of the Judicial Council to the Association of American Medical Colleges, he said: "Make your examinations at the end of the second year *honestly*, and require those men who cannot pass their examinations to go back or get out."

The American Medical School and Its Entrance Requirements.—Dr. David Starr Jordan, President of Leland Stanford Junior University contributed a paper of the above title, which was read by Dr. McIntire. It was stated that of the medical colleges of America, only those could live which became integral parts of universities. This applied as well to those which, without real university standards maintain a nominal connection, for purposes of advertising, with some university or college. The essentials of medical instruction were outlined as well equipped laboratories and hospitals, competent teachers, a standard of admittance which should exclude the ignorant and those incapable of scientific conceptions and a high standard of graduation, which should exclude unworthy men from the professional degree. The four years of a college course spent primarily on physiology, biology, and chemistry, and, secondarily, upon languages, literature, and history, gave a training to which the university could set its seal of approval. It was the opinion of the writer that the university should not be satisfied with less than seven years from the high school to the university degree of M.D. The writer further believed that the universities of America should begin with the junior year, leaving the freshmen and sophomore years to the colleges and the larger high schools and preparatory schools. By this arrangement all work of the university should be regarded as professional, confined to such subjects as were needed for professional training, and the profession of teaching among the rest, with such other subjects as might give breadth of vision or personal satisfaction, but not counting as constituents of a degree. In this case the course of medicine should be lengthened to five years by the inclusion of courses in science. The plan which seemed to Dr. Jordan most nearly in line with the development of the American university system was to begin all professional work with the third or junior year of the present American college. In this case the medical course might be strengthened with another year of further scientific requirements and further clinical experience at the end.

A Plea for the Impecunious Medical Student.—Dr. Roland G. Curtin of Philadelphia presented this paper, which was read by Dr. William L. Estes. It was observed that the length of time required for study had been gradually increased until at the present time the man was 28 or 29 when he commenced to practise. Considering that it might be five years before he made a living, he would be 33 or 35 years of age, when his most active period of life was almost over. Four suggestions were made for the assistance of the impecunious student and for the prevention of the medical profession being entirely in the hands of rich men's sons:

1. By commencing earlier the elementary studies necessary in his life work.

2. By having in each State at least one medical department of a university in which the man can obtain a medical education tuition free. It was suggested that in Pennsylvania one or more of the medical schools should unite with the State College and obtain the support of the State for this purpose.

3. By requesting the State to endow scholarships in the medical schools for those unable to pay.

4. The endowment of scholarships by rich men.

The Danger of Attempting Too Much.—Dr. Frederick H. Gerrish of Portland said that medical schools were designed primarily to make general practitioners, but that there was a marked tendency in the schools to give much valuable time to topics about which the practitioner had little occasion to know and to ignore or slight other things which he constantly or often needed. In the department of materia medica, for example, there was often presented an array of facts which was a burden to the mind. The teacher needed to have a keen sense of proportion and to know how to arrange a course of study which should be perfectly balanced. Specialties should be taught by experts. In short, the curriculum of the medical school should be arranged with particular reference to the needs of the general practitioner. There should be excluded all branches which were designed for mental discipline and those which did not have direct bearing upon the practice of medicine. The branches taught should be presented, not in their entirety, but only in such part as had the most practical reference to the needs of medical men. One danger of attempting too much was said to be that of setting up standards of an unreasonable height. However valuable might be the results of scientific methods in the medical school, they were of small moment if they failed to equip the student for encountering the practical part of his life work. Dr. Gerrish recognized that the studies of a medical curriculum must have a disciplinary influence upon the student's mind. The benefit, however, was incidental and not the principal issue. The real disciplinary work he believed should antedate the entrance of the man to the medical or other professional school

Dr. Clara Marshall of Philadelphia, Dean of the Woman's Medical College of Pennsylvania, in opening the discussion, claimed that the college curriculum could not be arbitrarily arranged, or if so arranged, it would not so remain; that a medical college curriculum was, unless some fortunate circumstance should determine otherwise, developed along the lines of the least resistance. In large cities, where it was easier to secure clinical material than to build extensive laboratories, the clinical side of the curriculum had usually been developed first and out of proportion to the first two years of the medical course; whereas, in the sparsely settled States of the West, patients being scarce, the tendency was to compensate for the lack of clinical material by erecting laboratories. This was especially true where an appropriation by the State was made for this purpose. In some States, in fact, only half a curriculum was possible, that is to say, the preclinical course only was provided for. An ideal curricu-

lum should be striven for, but there must be expected the modifications of environment.

Dr. Seneca Egbert of Philadelphia would advise young men to secure as liberal an education as possible before entering the medical school. While the medical school might not be highly cultural, he believed it to be developmental in the highest sense of the word. The tests of the State Board, while not what they should be, were, he believed, the best that could be obtained at present. While there should be a unification of curriculum, the question was regarded as largely one of environment.

Dr. William L. Estes of Bethlehem spoke of the great deficiency in the knowledge of anatomy exhibited by the students of all colleges of Eastern Pennsylvania. He believed that this fundamental branch should be continued in a practical way through the whole curriculum. The innovation in this country of a non-medical training in physics, anatomy, chemistry, and biology, he thought, might be detrimental to the general all-round medical trend which the student's education should assume.

Dr. J. W. Holland of Philadelphia thought that while training in universities at home and abroad made a very fine type of medical man it did not always make the very best doctor. He emphasized the fact, for which biological reasons had been given, that a man ought to be engaged at the business of life before he was 25 years of age.

Professor Schurmann, President of Cornell University, remarked that he represented a university which, beginning with the year 1908, would admit to its medical college only college graduates or persons of equivalent training. The question of such action, however, was not one to be settled by universal rule, but was dependent upon circumstances. He believed that while the elective principle in colleges was inevitable, it had been carried too far. In the years following the first two of the college course the student should study predominantly the sciences before entering upon the medical curriculum. Admitting that medical subjects and the pure sciences like physiology and anatomy should be taught by medical men, he asserted that the sciences like chemistry, physics, and biology which were not so closely intertwined with the medical sciences, could be taught by faculties other than medical. He would, therefore, eliminate chemistry, physics, and biology from the medical course, and the specialties he would put into the post-graduate course. There would then be room in between the two extremes for a good medical course.

Dr. Edward B. Heckel of Pittsburg deprecated the lack of unanimity in medical faculties and of concerted action among the heads of departments. The subject of psychology, he thought a neglected one in the medical schools.

What Are the Principles Underlying and What Provisions Should Be Included in a Medical Practice Act?—Dr. Alex. R. Craig of Philadelphia thought that as a matter of protection to the public, the law should determine the very lowest qualification a man might have and still be a safe practitioner of medicine. The matter of reciprocity should be one for each State to determine. In the event of a physician desiring to practise in another State, and since State Board examinations had been found faulty in determining the amount of knowledge a man had, it semed to him that some value should attach to resolutions passed by the man's own confrères as to his fitness to practise medicine.

Dr. Charles McIntire said that the provisions of a medical practice act should give no preponderance of power to the "dominant school." Other points emphasized by him were the necessity of a definition of what the practice of medicine really is, and that upon the medical examining board should be laid the responsibility of bringing to justice illegal practitioners of medicine.

Professor Raymond of Brooklyn favored the divided examinations, whereby at the end of the second year the student might undergo examinations in the so-called elementary or fundamental branches. Personally he objected to the elimination in the New York one board bill of the practice of medicine, therapeutics, and materia medica from the licensing examinations.

Dr. J. W. Holland of Philadelphia, in opposition to Professor Raymond, believed that any man who had qualified himself to a high standard in physiology, anatomy, chemistry, hygiene, pathology, surgery, diagnosis, etc., would know what to do in disease according to a certain school of medicine. He thought that such power as the determination of reputability of a college which it had been suggested should be given to the examining board, ought to be awarded with very great care.

Dr. Seneca Egbert of Philadelphia felt that legislators should be convinced of the fact that medical law was not for the benefit of the profession, but of the public. This idea should also be borne in mind by the profession.

Dr. J. B. McAlister of Harrisburg thought it possible to pass any medical bill in Pennsylvania could there but be a united profession back of it. No one school of medicine, he believed, should dominate the board.

Dr. Lee Smith of New York said that the New York Medical Practice Act, while having made a compromise in the elimination of the practice of medicine, materia medica, and therapeutics, was found to be working well. The examination of students in anatomy, physiology, and chemistry at the close of the second year was of great advantage. The essentials of these sciences, he believed, would remain in the students' minds.

Dr. Murray Galt Motter of Washington, D. C., believed that a medical law should eliminate politics from the State Board of Medical Examiners, and should provide that such examiners should have special qualifications for their duties. The ideal condition would be that the law should require the State Board to satisfy itself that the candidate was a safe man to practise medicine, and leave out all consideration of what subjects he should be examined in, and of the length of time devoted to his preparation, saying that, "If he is prepared, he is prepared." If a law like that were framed, he thought there would be no difficulty about licensing a man who had qualified by his practice in another State.

What Can the College and Fitting School Do to Aid in the Study of Medicine?—Dr. W. F. Mercer, professor of biology and geology in the Ohio University, read this paper, saying that he believed the place to save time was in the high school, also that to take some scientific work along with the other work of the college course was an advantage. He thought the medical man was making a mistake in considering that the graduates of literary colleges to-day were the same product as the graduates of twenty-five or fifty years ago. He thought it was not generally realized that the literary colleges of the present time were doing better and more work in literary science than the average medical college could possibly do. It seemed to him unfair that credit should not be given in the medical school for work done in the college.

What Are the Essential Subjects of General Information to Be Possessed by the Physician?—Rev. Dr. James D. Moffatt, President of Washington and Jefferson College, believed that as far as possible the traditional college course of study should be pursued before entering upon a medical education. He did not advise that all medical colleges should follow at once the example of Johns Hopkins and Harvard regarding the admission requirement. He conceded that there were some high school graduates who, going at once into the medical schools, would prove to be more successful physicians than some college graduates would ever become. It was his belief, however, that the college graduate who had made use of his opportunities would find himself better equipped to get the most out of his medical school op-

portunities than by saving those four years of time for his practice. In advocating generally the pursuit of a college course as preparatory to the study of medicine, he believed that that course would offer chemistry, physics, botany, and zoology, with abundant laboratory practice, taught without special reference to medicine, but more broadly, as perhaps, furnishing a better basis for special applications to the human body. The course should also include Latin and one or two modern languages, some higher mathematics, practice in English composition, some knowledge of English literature, history, a good course in psychology, anthropology, and sociology, and some knowledge of political science and ethics. Such a course would give an introduction to all the principal divisions of human knowledge and open the way for such further study as individual taste might induce.

Dr. M. J. Lewi, Secretary Board of Medical Examiners of New York, New York City, gave a résumé of the legal acts regulating the practice of medicine in New York.

Rev. A. B. Church, President of Buchtel College, believed that four years of college work was of value, if it did nothing more than change the ideals of young people. He did not favor the "short cuts," and felt that the time of development could not be ignored. He claimed that the best educated man, not the best instructed, was the man who possessed the greatest number of points of contact with the world of force.

Professor Blake of Lehigh University would like to see put in operation an arrangement by which the medical colleges would certify to the character of the work done in literary colleges and thereby make it possible for a man to get a medical degree in three years. Speaking for Lehigh, he felt that they were there prepared to give work in chemistry, physics, biology, and comparative anatomy, which was the equivalent of similar work given in any medical college in the country.

The Rev. G. L. Collie, President of Beloit College, who was unable to be present, communicated by letter his special interest in the Medical Practice Acts and the injustice done to independent colleges by these new laws. It was observed that such enactments were practically forcing many of the colleges to consider incorporating as two-year medical schools. A solution of the problem was said to reside in the amendment of the Medical Practice Acts so that the medical schools could give credit for pre-medical work done in the colleges.

Rev. William M. Crawford, D.D., President of Allegheny College, was represented in this discussion by a letter from Dr. Robert S. Breed of the Department of Biology and Geology of the Allegheny College. In the opinion of the writer the ideal preliminary training for medical students should include at least four year courses in biology, including, first, a course in general biology, which should deal not only with the general anatomy and physiology of a selected series of type animals and plants, but also a history of the development of the science, a study of the interrelation of species as included under the heading of ecology, a study of the distribution of living things in time and space, and, finally and most important, a study of the great laws and principles of biology with a discussion of the most important theories. This should be followed by courses in the comparative anatomy, histology, and embryology of vertebrates, with frequent references to the invertebrates. Additional training in botany, especially in general bacteriology, was highly desirable, together with training in laboratory technique. Dr. Breed asserted that it was possible to give this preliminary training in the ordinary college, and he believed it an advantage to have these subjects taught there rather than in the medical school because they were there taught from the standpoint of their general cultural value rather than from the standpoint of their practical application.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

University of the State of New York.

October 1, 2, and 3, 1907.

(Answer any 10 of the questions on each paper, but no more.)

ANATOMY.

1. Give the general characteristics of a vertebra. Describe the atlas.
2. Describe the ligaments of the hip joint.
3. Describe the varieties of muscular fiber and state where each variety is found.
4. Describe the branches of the arch of the aorta.
5. In what part of the body are the azygos veins? What purpose do they serve?
6. Give the anatomical name, the location, the average size, and the average number of the lymphatic glands of the ileum.
7. Describe the course of the fibers in the optic commissure.
8. Give the minute anatomy of the skin.
9. State the position, structure, length, and relations of the esophagus.
10. Give the gross anatomy of the eye.
11. Write a description of the thyroid gland.
12. What organs are wholly or partially retroperitoneal?
13. Give the relations of the stomach. What glands are found in the mucous membrane of the stomach?
14. Describe and locate the appendix vermiformis.
15. Give the course, caliber, relations, and structure of the ureter.

PHYSIOLOGY.

1. Define protoplasm and give the characteristic properties of living protoplasm.
2. Describe the heart sounds and state to what they are due.
3. Give the average normal temperature and the rate of pulse and of respiration in (*a*) the infant, (*b*) the adult, (*c*) the aged.
4. What digestive changes take place under the influence of saliva and of gastric juice?
5. State the origin and the functions of bile. What is the average quantity of bile secreted in twenty-four hours?
6. Describe the process by which digested food is absorbed.
7. Describe the physical properties of blood and name its constituents.
8. Describe the manner in which the vibrations of the air are transmitted through the auditory apparatus to be interpreted as sound.
9. State the origin of urea in the body. Mention the average amount of urea excreted in twenty-four hours.
10. Describe the physiological mechanism of perspiration.
11. Give the functions of (*a*) the medulla oblongata, (*b*) the cerebellum.
12. Give the mechanism of focal accommodation.
13. Describe (*a*) tonic muscular contraction, (*b*) clonic muscular contraction.
14. State in detail how the placenta performs its function.
15. Describe the physiological action of the kidney.

HYGIENE AND SANITATION.

1. Define (*a*) drainage, (*b*) sewage, (*c*) sewerage, (*d*) humidity, (*e*) ptomain.
2. In what part of an occupied room is the air most impure? Explain.
3. Explain the difference between hard water and soft water. State how a milk supply may be contaminated by impure water.
4. In what ways do forests benefit public health?
5. Diphtheria and variola are more prevalent in cold weather than in warm weather; explain why this is so. Give hygienic procedure in a case of diphtheria.
6. What methods should be employed for the prevention of yellow fever in the tropics?
7. Describe a procedure of disinfecting and of disposing of typhoid fever stools.
8. Mention some pathogenic bacilli found in drinking water and state what means should be employed to render such water potable.
9. What hygienic measures are advisable for the prevention and eradication of scorbutus?
10. What evil consequences may arise from the excessive use of tobacco?

11. What means should be employed under public health administration to prevent the spread of tuberculosis?
12. Mention *three* diseases induced by industrial pursuits. Explain how these diseases are caused.
13. Discuss the immunizing power of vaccination. State the possible dangers of vaccination.
14. What influences or conditions probably tend to make cerebrospinal meningitis epidemic? Mention prophylactic measures and describe the supposed causative germ.
15. Mention the various kinds of baths employed in health and in disease, and state the general hygienic rules to be observed in their use.

CHEMISTRY.

1. Define element, ion, specific gravity, reaction, an hydrid.
2. Give the chemical reaction of (*a*) saliva, (*b*) gastric juice, (*c*) urine, (*d*) mother's milk, (*e*) synovial fluid.
3. Give the laboratory preparation of O, of CO_2, and of H_2S. Give the properties of *one* of the products mentioned.
4. What is the chemical name of (*a*) common table salt, (*b*) soot, (*c*) vinegar, (*d*) blue vitriol, (*e*) Rochelle salt?
5. Give the formula, method of preparation, and principal uses of chloride of lime.
6. Describe a test for biliary acids and their salts.
7. State the changes occurring in the air and in the blood in respiration.
8. Give the formula, uses, and properties of hydrogen dioxide.
9. Give a test for the detection of alum in baking powder.
10. State the source of *each* of the following acids: (*a*) hydrochloric, (*b*) sulphuric, (*c*) lactic, (*d*) tannic, (*e*) tartaric.
11. How may carbolic acid be prepared? Mention a chemical antidote for carbolic acid poisoning.
12. Describe (*a*) a qualitative test for sugar in the urine, (*b*) a quantitative test for sugar in the urine.
13. What is the action of a solution of permanganate of potassium used as a disinfectant?
14. Give the names and state the formulas of the different compounds used to produce general anesthesia.
15. Complete the following equation:

$$2KI + MnO_2 + 2H_2SO_4 =$$

SURGERY.

1. Mention the indications for draining a wound, and describe the methods of securing drainage.
2. Define (*a*) lipoma, (*b*) angioma, (*c*) osteoma, (*d*) myxoma, (*e*) carcinoma. Give the symptoms of scirrhous carcinoma of the breast.
3. Describe in detail amputation of the forearm.
4. Give the treatment of a compound fracture of the shaft of the tibia.
5. Give the symptoms and the treatment of a forward dislocation of the head of the humerus.
6. Describe the injury received by the various tissues in a severe sprain of the ankle and outline the treatment.
7. What should be the immediate procedure and the subsequent surgical dressing in a case of talipes equinovarus in a newborn infant?
8. Give the surgical treatment of hemorrhage. Describe (*a*) intravenous saline infusion, (*b*) hypodermoclysis.
9. Give the symptoms of vesical calculus. Describe a method of proving the presence of a vesical calculus.
10. Describe the preparation necessary for an aseptic laparotomy as regards (*a*) the patient, (*b*) the surgeon, (*c*) the assistants, (*d*) the instruments, (*e*) the operating room.
11. Differentiate between fistula and sinus. Describe the surgical treatment of fistula in ano.
12. Mention the most common causes of iritis. Give the symptoms and the surgical treatment of iritis.
13. What conditions render tonsillotomy advisable and how is the operation performed?
14. When should skin grafting be employed? Describe an approved method of skin grafting.
15. Describe in detail the treatment of a scalp wound when a fractured skull is suspected.

OBSTETRICS AND GYNECOLOGY.

1. State the indications for the use of the intrauterine douche and mention the objections to its use.
2. Give the physiological explanation of fecundation.
3. Describe the permanent changes in the female sexual organs following parturition.
4. What are the causes of toxemia of pregnancy? Give the prophylactic management of such a condition.
5. What are the varieties of placenta previa and how should each variety be managed?
6. Under what conditions does version become imperative? How should version be performed?
7. How is external palpation applied to the diagnosis of the position of the fetus?
8. In the after-coming head, what principles should be applied to secure a living child? How may a dead fetus influence labor?
9. What conditions demand the induction of abortion prior to quickening and what is the technique of the procedure?
10. Give the prognosis and the treatment of a uterine fibroid complicating pregnancy.
11. State the pathology, symptoms, and surgical treatment of endometritis.
12. Differentiate between menorrhagia and metrorrhagia. Give the surgical management of each.
13. Define atresia of the vagina and state the method of relief.
14. Give the etiology and the surgical treatment of erosions of the cervix uteri.
15. Give the causes and the dangers of ophthalmia neonatorum and state the preventive management.

PATHOLOGY AND BACTERIOLOGY.

(Of the ten questions to be answered, select at least four from each group.)

GROUP I.—1. Describe (*a*) the syphilitic lesions of the skin, (*b*) the lesions in lupus.
2. What pathological changes in lung tissue occur in the various stages of lobar pneumonitis?
3. Describe the changes that occur in the structure of the crystalline lens in cataract.
4. What is leucocytosis and to what conditions may it be due?
5. Describe and illustrate by a drawing or otherwise, the microscopical appearance of an adenoid.
6. Describe the macroscopical and the microscopical appearance of carcinoma of the breast.
7. What pathological conditions are productive of icterus?
8. Describe the changes that occur in degeneration of muscle.

GROUP II.—9. What are the three basic forms of bacteria? Describe each form by drawing or otherwise.
10. Name and describe the microorganism of typhoid fever.
11. Describe the tubercle bacillus. Give a method of microscopical demonstration of the tubercle bacillus.
12. What is a pure culture? Mention *three* of the most useful culture media.
13. Describe the specific organism of tetanus and state its peculiar culture characteristics.
14. Name and describe a malarial parasite.
15. What is a diplococcus? Give the names of *two* pathogenical diplococci.

DIAGNOSIS.

1. What vertebræ are directly back of the following points: (*a*) xiphoid appendix, (*b*) Ludwig's angle (angulus Ludovici), (*c*) suprasternal notch?
2. What is the significance of (*a*) albumin in the urine, (*b*) casts in the urine?
3. Make a differential diagnosis of the sore throat of diphtheria, scarlatina, and acute tonsillitis.
4. What are the symptoms of incipient tuberculosis? With what other conditions may incipient tuberculosis be confounded?
5. Give the normal boundaries of cardiac dullness. What conditions may increase the area of cardiac dullness?
6. Describe the stools in (*a*) enteritis, (*b*) dysentery.
7. What is the significance of (*a*) bronchial breathing, (*b*) crepitant râles, (*c*) vesicular breathing?
8. Make a differential diagnosis of gastric ulcer, cancer of the stomach, and stenosis of the pyloric end of the stomach.
9. What is the incubation period of (*a*) rubeola, (*b*) parotitis, (*c*) variola, (*d*) varicella, (*e*) scarlatina?
10. Describe an attack of hepatic colic due to biliary calculi.
11. Give the topography of the valves of the heart on the chest wall. Where is a mitral obstructive murmur heard loudest?
12. Give the clinical signs of pus formation and retention.
13. What are the diagnostic features of tabes dorsalis?
14. Give an estimate of the value of the *x*-ray as an aid to diagnosis.
15. State the diagnostic value of a blood examination in (*a*) chlorosis, (*b*) appendicitis, (*c*) trichinosis.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

UNIVERSITY OF THE STATE OF NEW YORK.

October 1, 2, and 3, 1907.

ANATOMY.

5. The azygos veins are found in the abdominal and thoracic cavities. They serve as a connecting link between the superior and inferior venæ cavæ, and also collect blood from the intercostal spaces.

PHYSIOLOGY.

1. Protoplasm is a jelly-like substance which is the physical basis of life.

The characteristic *properties* of living protoplasm are: (1) irritability, or power of responding to a stimulus; (2) power of movement; (3) power of assimilation; (4) power of growth; (5) power of excretion, and (6) power of reproduction.

2. The *causes* producing the *first* sound of the heart are not definitely ascertained. The following are supposed to be causatory factors: (1) The vibration and closure of the auriculo-ventricular valves, (2) the muscular sound produced by the contraction of the ventricles, and (3) the cardiac impulse against the chest wall.

The *second* sound is caused by the vibration due to the closure of the semilunar valves.

3.—

Average normal:	In Infant	In Adult	In Aged
Temperature.....	About 37.1° C.	About 37.1° C.	About 37.4° C.
Rate of Pulse.....	" 120 a min	" 72 a min	" 80 a min
Rate of Respiration..	" 40 "	" 16 "	" 18 "

4. The *saliva*, by means of the ptyalin, converts starches into dextrin and maltose.

The gastric juice, by means of the pepsin, converts proteids into proteoses and peptones; the casein of milk is also curdled.

5. Bile is a secretion product of the liver.

The functions of the bile are: (1) To assist in the emulsification and saponification of fats; (2) to aid in the absorption of fats; (3) to stimulate the cells of the intestine to increased secretory activity, and so promote peristalsis, and at the same time it tends to keep the feces moist (4) to eliminate waste products of metabolism, such as lecithin and cholesterin; (5) it has a slight action in converting starch into sugar; (6) it neutralizes the acid chyme from the stomach and thus inhibits peptic digestion; (7) it has a very feeble antiseptic action.

The average quantity of bile secreted in twenty-four hours varies from about 500 c.c. to 900 c.c.

7. *The physical properties of blood*: Fluid, somewhat viscid, red, specific gravity from 1055 to 1062, alkaline reaction, saltish taste, characteristic odor, variable temperature (average about 100 degrees F.).

The *constituents of the blood* are plasma and corpuscles. The *plasma* consists of water and solids (proteids, extractives and inorganic salts). The *red corpuscles* consist of water and solids (hemoglobin, proteids, fat, and inorganic salts). The *white corpuscles* consist of water and solids (proteid, leuconuclein, lecithin, histon, etc.).

8. "The waves of sound are gathered together by the pinna and external auditory meatus, and conveyed to the membrana tympani. This membrane, made tense or lax by the action of the tensor tympani and laxator tympani muscles, is enabled to receive sound waves of either high or low pitch. The vibrations are conducted across the middle ear by a chain of bones to the foramen ovale, and by the column of air of the tympanum to the foramen rotundum, which is closed by the second membrana tympani, the pressure of the air in the tympanum being regulated by the Eustachian tube. The internal ear finally receives the vibrations, which excite vibrations successively in the perilymph, the walls of the membranous labyrinth, the endolymph, and, lastly, the terminal filaments of the auditory nerve, by which they are conveyed to the brain."—(Brubaker's *Physiology.*)

9. *Urea* is derived from the nitrogenous food ingested: it is manufactured by the cells of the liver. The average amount of urea excreted in twenty-four hours is about five hundred grains.

11. (*a*) *The functions of the medulla* are: (1) It is a conductor of nervous impulses or impressions from the cord to the cerebrum, from the brain to the spinal cord, also of co-ordinating impulses from the cerebellum to the cord; (2) it contains collections of gray matter which serve as special nerve centers for the following functions or actions: Respiration, salivary secretion, mastication, sucking, deglutition, speech production, facial expression; it also contains the cardiac and vasomotor centers.

(*b*) *The functions of the cerebellum* are: (1) co-ordination, (2) equilibrium.

12. "*Mechanism of Accommodation.*—The lens is an elastic structure, and when released from the flattening influence of its suspensory ligament tends to assume a spherical shape. During accommodation the ciliary muscle (especially the circular fibers) contracts, drawing forward the chorioid and relaxing the suspensory ligament; this diminishes the tension of the lens capsule and allows the inherent elasticity of the lens to increase its convexity. The change in curvature affects chiefly the anterior surface of the lens. This is Helmholtz's theory and the one usually accepted. Lately Tscherning has advanced a different theory; he maintains that the ciliary muscle increases the tension of the suspensory ligament during contraction and that this causes peripheral flattening of the lens with bulging anteriorly at its center. The act of accommodation is accompanied by contraction of the pupil, and (in binocular vision) by convergence of the visual lines." (May's *Diseases of the Eye.*)

13. In *tonic* muscular contraction the muscle remains for some time in a state of rigid contraction. In *clonic* contraction the muscle alternately contracts and relaxes.

14. "For the purposes of understanding its general functions it is sufficient to recall that the placenta consists essentially of vascular chorionic papillæ from the fetus bathed in large blood-spaces in the decidual membrane of the mother. The fetal and the maternal blood do not come into actual contact; they are separated from each other by the walls of the fetal blood-vessels and the epithelial layers of the chorionic villi, but an active diffusion relation is set up between them. Nutritive material, proteid, fat, and carbohydrate and oxygen pass from the maternal to the fetal blood, and the waste products of fetal metabolism—carbon dioxide, nitrogenous wastes, etc.—pass from the fetal to the maternal blood. . . . . We are far from having data that would justify us in supposing that the exchange between the two bloods is effected by the known physical processes of osmosis, diffusion, and filtration. . . . . It is generally assumed that the chorionic villi play an active part in the process." (Howell's *Text-book of Physiology.*)

HYGIENE AND SANITATION.

1. (*a*) *Drainage* is the removal of the surface water and soil water

(*b*) *Sewage* is the matter found in sewers, and consists chiefly of excreta and the waste matter from kitchens.

(*c*) *Sewerage* is the process of systematically collecting and removing sewage from houses or other buildings; also the system of pipes, etc., arranged for the carrying off of sewage.

(*d*) *Humidity* is the degree of water vapor in the air.

(*e*) *Ptomain* is a basic compound, containing nitrogen, and produced by bacteria during the putrefaction of animal or vegetable matter.

2. The foulest air will be found nearest the ceiling; there is a tendency for the used air to rise.

3. *Hard* water forms a curdy deposit with soap and contains an excess of calcium and magnesium salts; *soft* water allows soap to dissolve in it without precipitation.

A milk supply may be contaminated by impure water, by being adulterated with it; by the cans, containers, or cows' udders being washed with it.

5. Ventilation is less satisfactory and the changes in temperature are greater and more frequent in the cold weather; hence vitality is lowered and there is a greater liability to take diseases.

6. To prevent yellow fever in the tropics: All cases of the disease should be isolated; houses should be protected by mosquito netting; mosquitos should be killed; swamps should be drained.

8. *Some pathogenic bacteria found in drinking water* are: Eberth's bacillus of typhoid, Koch's comma bacillus of cholera, *Bacillus anthracis, Staphylococcus pyogenes aureus, Streptococcus pyogenes.*

To render such water potable: Boil the water and filter it. The best safeguard by the latter method is to use the Pasteur-Chamberland filter or some other porcelain filter.

9. "Abundant fresh air and sunlight and a diet of fresh vegetables, especially potatoes, spinach, and fruits, with meat, eggs, fish, etc. If the stomach is irritable fresh milk, eggs, and lime, orange or lemon juice may almost always be tolerated. * * * A mouth wash of saturated boric acid, alternating with a 2 per cent. solution of potassium permanganate, should be used every

hour or two until the gums are healed." (From Thompson's *Practical Medicine.*)

10. "The continued use of tobacco, by smoking or chewing it to excess, produces granular inflammation of the fauces and pharynx, atrophy of the retina, dyspepsia, lowered sexual power, sudden faints, nervous depression, cardiac irritability, and occasionally angina pectoris. Used by the young, it hinders the development of the higher nerve centers and impairs the nutrition of the body by interfering with processes of digestion and assimilation. It has been credited with causing cancer of the lips and tongue, blunting the moral sense, mental aberration and even insanity." (Potter's *Materia Medica, etc.*)

11. "The preventive measures which may be taken to reduce tuberculosis may be summarized as follows: (1) The compulsory notification of phthisis. (2) The removal of those conditions of domicile and of occupation which are known to promote the incidence of the disease, including the regulation of certain dusty trades. (3) The diffusion of knowledge (by medical men, leaflets, etc.) regarding the nature and modes of spread of the disease, and the precautions which should be taken in order to prevent its extension. (4) The testing of sputum and other suspected discharges, and of milk, meat, etc., supposed to be tuberculous—reports to be furnished free of charge. (5) Local authorities to undertake, without charge, the disinfection of houses recently occupied by phthisical persons. (6) The establishment of sanatoria and isolation accommodation for the cure of phthisical patients, and the isolation of those who are a distinct source of danger to fellow lodgers or workers. (7) The enforcement of measures against spitting in public conveyances and in places of public resort. (8) The efficient sanitary supervision of dairy farms, dairies, and milkshops. The periodical veterinary inspection and testing (by tuberculin) of milch cows, and the slaughter of tuberculous animals. The prohibition of the sale of milk of cows affected with tuberculosis. (9) The proper inspection of meat in public abattoirs, and the adoption of due precautions for the control of imported meat and milk." (Parkes' *Practical Hygiene.*)

CHEMISTRY.

1. An *element* is a substance which cannot, by any known means, be split up into dissimilar substances.

An *ion* is the primary product of electrolysis.

Specific gravity of a substance is the weight of a given volume of that substance as compared with the weight of an equal volume of some other substance taken as a standard of comparison, under like conditions of temperature and pressure.

Reaction has two meanings: (1) It is the mutual chemical action of two substances upon each other. (2) It is the action of substances upon certain organic pigments.

An *anhydrid* is an oxide capable of combining with water to form an acid.

2. The chemical reaction of (*a*) saliva, is alkaline; (*b*) gastric juice, is acid; (*c*) urine, is acid: (*d*) mother's milk, is alkaline; (*e*) synovial fluid, is alkaline.

3. O is prepared by heating a mixture of equal parts of potassium chlorate and manganese dioxide. The potassium chlorate gives up all of its O:

$$2KClO_3=2KCl+3O_2.$$

CO_2 is prepared by acting on calcium carbonate with hydrochloric acid:

$$CaCO_3+2HCl=CaCl_2+H_2O+CO_2$$

H_2S is prepared by acting on ferrous sulphide with dilute sulphuric acid:

$$FeS+H_2SO_4=FeSO_4+H_2S.$$

The *properties of oxygen*: It is a colorless, odorless, tasteless gas; it is sparingly soluble in water; it has a strong tendency to enter into combination with other elements; it is necessary for respiration, and is both combustible and a supporter of combustion.

4. The chemical name of (*a*) common table salt, is sodium chloride; (*b*) soot, is carbon; (*c*) vinegar, is acetic acid; (*d*) blue vitriol, is cupric sulphate; (*e*) Rochelle salt, is potassium sodium tartrate.

5. CHLORIDE OF LIME. *Formula*: $Ca(OCl)_2+CaCl_2$. *Preparation*: It is made by treating slaked lime with chlorine:

$$2Ca(OH)_2+2Cl_2=2H_2O+Ca(OCl)_2+CaCl_2.$$

Principal uses: As a disinfectant and for bleaching.

6. *The Pettenkofer test*: Dissolve one or two drops of a solution of cane sugar 1:4 in the liquid to be examined; shake the mixture and float it carefully upon concentrated H_2SO_4. In the presence of bile acids the solution becomes turbid at the zone of junction of the two layers; this is soon replaced by a deep reddish purple zone, which extends upward and downward.

7. Changes occurring in the *air* is respiration:

	Expired Air.	Inspired Air.
Oxygen	16.6 per cent.	21 per cent.
Nitrogen	79 per cent.	79 per cent.
Carbon dioxide	4.4 per cent.	0.04 per cent.
Other gases	Often present.	Rare.
Watery vapor	Saturated.	Variable.
Temperature	That of body.	Variable.
Volume	Diminished.	Varies.
Bacteria	None.	Always present.
Dust	None.	Always present.

Changes occurring in the *blood* in respiration: Respiration renders the blood red in color, warmer, adds oxygen and takes away carbon dioxide, makes it more coagulable and of more uniform composition.

8. HYDROGEN DIOXIDE. *Formula*: H_2O_2.

Uses: It is used as a disinfectant, as an oxidizing agent, as an antiseptic, for bleaching, and for renovating old oil paintings.

Properties: It is a colorless, syrupy liquid, heavier than water, and having a metallic taste.

9. "Alum is tested for (in baking powder) by burning a small quantity of the sample to an ash, which is then treated with boiling water and filtered. If on the addition of ammonium chloride to the filtrate a flocculent precipitate is formed, this will indicate the presence of alum in the sample." (*Reference Handbook of the Medical Sciences.*)

10. The *source* of (*a*) *hydrochloric acid*: The fumes produced by the action of H_2SO_4 on NaCl are dissolved in H_2O.

(*b*) *Sulphuric acid*: It is produced by the combustion of S and the oxidation and hydration of the resulting SO_2 by means of HNO_3.

(*c*) *Lactic acid*: It is produced by the lactic fermentation of milk-sugar.

(*d*) *Tannic acid*: From nutgalls.

(*e*) *Tartaric acid*: From the juice of the grape.

11. *Carbolic acid* may be prepared by heating phenyl iodide with potassium hydroxide:

$$C_6H_5I+KOH=KI+C_6H_5OH.$$

Chemical antidotes for carbolic acid poisoning are the soluble sulphates, such as sodium sulphate or magnesium sulphate.

12. "(*a*) *Qualitative test for sugar in the urine*: Render the urine strongly alkaline by addition of Na_2CO_3. Divide about 6 c.c. of the alkaline liquid in two test tubes. To one test tube add a very minute quantity of powdered subnitrate of bismuth, to the other as much powdered litharge. Boil the contents of both tubes. The presence of glucose is indicated by a dark or black color of the bismuth powder, the litharge retaining its natural color." (Witthaus' *Essentials of Chemistry.*)

(*b*) Method for the *quantitative estimation of sugar in urine*: *Fehling's method*: The solution is made as follows:

I. Dissolve cupric sulphate	51.98 gm.
in water to	500.00 c.c.
II. Dissolve Rochelle salt	259.9 gm.
in sodium hydroxide soln. sp. gr. 1.12 to	1,000 c.c.

(Piffard).

When required for use, one volume of I. is to be mixed with two volumes of II. The copper contained in 10 c.c. of this mixture is precipitated completely, as cuprous oxide, by 0.05 gm. of glucose.

"To determine the quantity of sugar, place 10 c.c. of the mixed soln. in a flask of about 250 c.c. capacity, dilute with H_2O to about 30 c.c., and heat to boiling. On the other hand, the urine to be tested is diluted and thoroughly mixed with four volumes of H_2O if it be poor in sugar, or with nine volumes of H_2O if highly saccharine, and a burette filled with the mixture. When the Fehling soln. boils, add a few gtt. NH_4HO and then 5 c.c. of the urine from the burette, boil again, and continue the alternate addition of diluted urine and boiling of the mixture until the blue color is quite faint. Now add the diluted urine in quantities of 1 c.c. at a time, boiling after each addition until the blue color just disappears. Have ready a small filter, and, having filtered through it a few gtt. of the hot mixture, acidulate the filtrate with acetic acid, and add to it 1 gtt. soln. of potassium ferrocyanide. If a brownish tinge be produced, add another ½ c.c. of dil. urine to the flask, boil, and test with ferrocyanide as before. Continue this proceeding until no brown tinge is produced. The burette reading, taken at this point, gives the number of c.c. of dilute urine containing 0.05 gm. glucose, and this divided by 5 or 10, according as the urine was diluted with 4 or 9

volumes of H_2O, gives the number of c.c. of urine containing 0.05 gm. sugar. The number of c.c. urine passed in twenty-four hours divided by 20 times the number of c.c. containing 0.05 gm. glucose, gives the elimination of glucose in twenty-four hours in grams.

Example: Urine in 24 hours =2,436 c.c.
Fehling's soln. used = 10 c.c.
Urine diluted with 4 vols. H_2O
Burette reading = 18.5 c.c.

$$\frac{18.5}{5} = 3.7 = \text{c.c. urine containing 0.05 gm. glucose.}$$

$$\frac{2{,}436}{3.7 \times 20} = 32.92 = \text{grams glucose eliminated in 24 hours."}$$

(Witthaus' *Urinalysis.*)

13. Potassium permanganate acts as a disinfectant by oxidizing the organic matter with which it comes in contact.

14. The chief general anesthetics, with their formulæ, are: Chloroform, $CHCl_3$; ether $(C_2H_5)_2O$; nitrous oxide, N_2O; ethyl chloride, C_2H_5Cl.

15. $2KI + MnO_2 + 2H_2SO_4 = K_2SO_4 + MnSO_4 + 2H_2O + I_2$.

PATHOLOGY AND BACTERIOLOGY.

3. "*Senile cataract* results from shrinkage of the nucleus, together with the lens fibers, and presence of fluid in the spaces thus created. The lens fibers then swell, become cloudy, and disintegrate. The nucleus usually remains unchanged." (May's *Diseases of the Eye.*)

4. *Leucocytosis* is an increase in the number of leucocytes in the peripheral blood.

It may be due to inflammations, hemorrhage, various infections, certain toxic conditions. It is also found physiologically or normally: During digestion, during pregnancy, after parturition, after violent exercise, massage, and in the new-born child.

7. *Icterus* may be caused by: Certain poisons, infections, pernicious anemia, pronounced degeneration of the liver cells, obstruction of the bile duct, catarrh of the bile ducts, parasites or other foreign bodies in the bile ducts, and the pressure of tumors in adjacent parts.

9. The three basic forms of bacteria are: (1) The *coccus*, which is round or oval, and may appear singly, in pairs, in groups of four, in chains, or in bunches. (2) The *bacillus*, which is rod shaped, with the longer sides parallel, and the short ends either straight, rounded, or concave. (3) The *spirillum*, which is spiral.

10. Typhoid fever is caused by the *Bacillus typhosus* of Eberth. This organism is rod shaped, with rounded ends, is from 2 to 4 mikrons in length, and about three-fourths of a mikron in breadth; it does not stain by Gram's method, but stains with all the anilin dyes; it has flagella, no spores, is aërobic and facultative anaërobic, and is motile.

11. The tubercle bacillus is rod shaped, is from 1½ to 3½ mikrons in length and about one-third to one-half a mikron in breadth, is a strict parasite, is not motile and has no flagella.

To demonstrate the existence of tubercle bacilli in the sputum: The sputum must be recent, free from particles of food or other foreign matter; select a cheesy-looking nodule and smear it on a slide, making the smear as thin as possible. Then cover it with some carbolfuchsin, and let it steam over a small flame for about two minutes, care being taken that it does not boil. Wash it thoroughly in water and then decolorize by immersing it in a solution of any dilute mineral acid for about a minute. Then make a contrast stain with solution of Loeffler's methylene blue for about a minute; wash it again and examine with oil immersion lens. The tubercle bacilli will appear as thin red rods, while all other bacteria will appear blue.

12. A pure culture is a culture in which only one microorganism is present.

Three-culture media: Bouillon made from beef extract, gelatin, and agar.

13. The bacillus of tetanus is characterized by its peculiar spore, formed at one end of the bacillus, and giving it the appearance of a pin; it is purely anaërobic, and cannot be developed at all in the presence of oxygen. It generally comes from the soil, and is found in penetrating wounds. It appears in two forms, the spore-bearing form, as described above, and the vegetative form, which is a short bacillus with rounded ends, and which may occur singly or in pairs, or may form long filaments. It grows in gelatin stab cultures in the middle of the medium, and the colonies look something like a fir tree; its growth is slow, and a disagreeable odor is at the same time emitted. In bouillon, it grows near the bottom of the tube, and produces gases.

15. A *diplococcus* is a form of bacteria made up of two cocci attached to each other (in pairs).

Two pathogenic diplococci: *Diplococcus pneumoniæ* and *Diplococcus intracellularis meningitidis.*

DIAGNOSIS.

1. The vertebra directly back (*a*) of *xiphoid appendix*, is the tenth dorsal; (*b*) of *Ludwig's angle*, is the third dorsal; (*c*) of *suprasternal notch*, is second dorsal.

2. (*a*) *Albumin* is found in the urine: "(1) In fevers, as typhoid and pneumonia. (2) In valvular heart lesions, degeneration of the heart muscles, diseases of the coronary arteries, impeded pulmonary circulation, in pregnancy by pressure upon the renal veins, in intestinal catarrh, and in Asiatic cholera. (3) In purpura, scurvy, leukemia, pernicious anemia, jaundice, diabetes, and syphilis. (4) After taking lead, mercury, iodine, phosphorus, arsenic, antimony, chloroform, cantharides, oxalic, carbolic, salicylic or the mineral acids, turpentine and nitrates. (5) In large amounts in acute nephritis and chronic parenchymatous nephritis; in small amounts in chronic interstitial nephritis and amyloid kidney." (Witthaus' *Essentials of Chemistry.*)

(*b*) "*Casts* in the urine occur in nephritis; and different varieties are found in the different forms of that disease. *Hyaline* casts occur in all forms of nephritis, in congestion of the kidneys, in jaundice, and even in health. *Waxy* casts occur especially in chronic parenchymatous nephritis. *Epithelial* casts occur especially in acute parenchymatous nephritis. *Granular* casts are especially common in chronic nephritis, but they may occur in acute nephritis. *Fatty* casts occur chiefly in chronic parenchymatous nephritis. *Blood* casts occur in acute and chronic hemorrhagic nephritis. *Pus* and *bacterial* casts are occasionally met with in suppurative nephritis." (From Stevens' *Practice of Medicine.*)

3. "In *diphtheria* the palate, fauces, or pharynx are of a vivid red color, coated in parts with a thick grayish white exudation, which, when peeled off, leaves the subajacent membrane red and bleeding, and is soon renewed. In *scarlatina* the throat may be inflamed, but not ulcerated, or both inflamed and ulcerated, or with both these conditions and accompanied with sloughing. In *acute tonsilitis* the pain is augmented by swallowing, the affected tonsil is swollen, and projects towards the middle line, the mucous membrane is red and covered with mucus." (From Fenwick's *Medical Diagnosis.*)

4. The early manifestations of pulmonary tuberculosis are: (1) *Physical signs*: Deficient chest expansion, the phthisical chest, slight dullness or impaired resonance over one apex, fine moist râles at end of inspiration, expiration prolonged or high pitched, breathing interrupted. (2) *Symptoms*: General weakness, lassitude, dyspnea on exertion, pallor, anorexia, loss of weight, hemoptysis, slight fever, and night sweats.

Incipient tuberculosis may be confounded with typhoid, malaria, and capillary bronchitis.

5. The normal boundaries of absolute cardiac dullness are: (1) A line drawn from the center of the sternum, on a level with the fourth costal cartilages, to the apex of the heart; (2) a line from the same point down the left edge of the sternum; (3) a line joining the ends of (1) and (2).

The area of cardiac dullness is *increased* in: Hypertrophy of the heart, dilatation of the heart, pericardial effusion.

6. (*a*) In *enteritis* the stools are generally thin and watery, but may be pultaceous; the color varies according to the quantity of bile present; undigested food, mucus, epithelium, and microorganisms of various sorts are present.

(*b*) In *dysentery* the stools contain mucus and blood, are accompanied with much tenesmus and pain; are very small and frequent, sometimes being passed every few minutes; contain little fecal matter; contain the *Ameba dysenteriæ* or Shiga's bacillus.

7. (*a*) *Bronchial breathing* may indicate consolidation of the lung, or a large cavity communicating with a bronchus; it is heard in phthisis, lobar pneumonia, and hemorrhagic infarction; it is also heard normally over the trachea and large bronchi.

(*b*) *Crepitant râles* may indicate the first stage of lobar pneumonia, or pulmonary edema and atelectasis.

(*c*) *Vesicular breathing* may be "compensatory" when the other lung is out of use; it may indicate emphysema, bronchitis, phthisis, defective lung expansion, pleuritic effusion; it is also heard normally over a large portion of the chest.

8. *Gastric ulcer* is generally caused by injury or bacteria; is most apt to occur between the ages of twenty and forty-five; after eating there is pain localized in the stomach, vomiting occurs soon after eating; hematemesis is common, there is localized tenderness over the stomach,

and examination shows an excess of free HCl.

Cancer of the stomach does not usually occur before forty years of age, is more common in males, the pain is localized and constant, vomiting is copious and occurs some time after eating; the vomitus contains "coffee ground" material; hemorrhages are common; a tumor may be palpated, and examination of the gastric contents shows absence of free HCl and presence of lactic acid; severe anemia and cachexia are also present.

In *stenosis of the pyloric end of the stomach* there will be found a distended stomach; there is vomiting at long intervals, the vomitus being copious and consisting of stagnant fluid with undigested particles of food; the *Sarcina ventriculi* and many bacteria may be present.

11. *Topography of the valves of the heart on the chest wall*: "The *right auriculo-ventricular valves* are situated behind the sternum above the level of the fourth costal cartilage; the *left auriculo-ventricular valves* are opposite the third intercostal space, about one inch to the left of the sternum; the cusps of these valves extend as low as the fifth costal cartilage. The *pulmonary valves* lie immediately behind the junction of the third left costal cartilage with the sternum; the *aortic valves* are behind the upper border of the third intercostal space just at the left side of the sternum." (Holden.)

A mitral obstructive murmur is loudest at the apex.

15. (*a*) In *chlorosis* a blood examination shows marked diminution of hemoglobin, slight diminution of red cells, poikilocytosis, and in severe cases nucleated red cells. The diagnosis is certain.

(*b*) In *appendicitis* leucocytosis is fairly constant, except in the mildest and most severe cases. The blood examination will differentiate this condition from typhoid. It is a help in diagnosis, but not absolutely certain.

(*c*) In *trichinosis* there is a leucocytosis with a very pronounced eosinophilia. It is of great diagnostic value.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.		
Alabama*	W. H. Sanders, Montgomery	Montgomery		
Arizona*	Ancil Martin, Phoenix	Phoenix	April	6

Medical Items.

Treatment of Perianal and Perirectal Abscesses.—E. H. Thrailkill says that the physician should never take a patient's diagnosis for a disease of the rectum, but examine him thoroughly before treatment is instituted. As much antiseptic precaution should be employed here as in surgery of other parts of the body. A straight bistoury is preferable to a curved one, because the surgeon can be more certain as to the exact location of its point. The incison should be wider than the widest portion of the induration or abscess. A curette should never be used in cleaning out these abscess cavities owing to the danger of opening up a new field for bacterial invasion. The abscess cavity should be packed firmly at the first dressing to prevent subsequent hemorrhage. The patient should be well nourished and allowed the freedom of his room as early as possible.—*The Journal of the Kansas City Medical Society.*

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service for the week ending January 24, 1908:

BLOOD REACTIONS OF INFLAMMATION; AND THE DIAGNOSTIC PREVENTION OF THE TERMINAL STAGES OF INFECTIONS OF THE APPENDIX AND GALL-BLADDER.

BY W. A. BARTLETT, M.D., AND E. E. SMITH, M.D.

NEW YORK.

PART I. BLOOD REACTIONS OF INFLAMMATION;* BY E. E. SMITH, M.D.

DURING active inflammatory processes a considerable number and variety of changes occur in the circulating blood. Of these, I wish at this time to consider the following: (*a*) The absolute number of leucocytes. (*b*) The relative number of polymorphonuclear leucocytes. (c) The degree of fibrin formation.

It is an established fact that many times during the active period of inflammation there is an increase in the absolute number of leucocytes in the circulating blood. This increase is known to be a reaction resulting from the production at the site of the process of positive chemotaxic substances—substances that, to employ purely physical terms, decrease the surface tension of the leucocytes, thereby bringing about their movement in the blood stream towards the source of the chemotaxic substances, namely, in the cases under consideration, towards the site of the inflammation.

Substances capable of producing positive chemotaxis may be derived, under the conditions we are considering, from at least two sources: First, from the tissue cells, where the production is a result of the defensive reaction to injury on the part of the cells; and, second, from infecting bacterial organisms, the exciting cause in many instances of the injury which is the occasion of the inflammatory process. The influence of the chemotaxic substances thus produced extends, in any considerable process, throughout the entire blood stream, being greater nearer the point of injury, the source of the substances in question, and becoming less as the distance from the point increases, establishing thereby a migration of the leucocytes from their more or less remote repositories and seats of origin, bringing an increased number of them into the blood stream on their way to the diseased tissue; that is to say, producing an absolute leucocytosis.

With reference to the source of the chemotaxic substances, we may distinguish two classes of inflammation: (1) Where the substances are largely produced by the defending tissue cells. (2) Where the cells and invading bacteria both contribute materially to their production.

As an example of the first class, I will mention the exudative stage of inflammation in an active appendicitis. Here we have a rudimentary organ many times suffering a maximum of injury from a minimum of bacterial invasion, in which the tissue reaction is out of proportion to the extent of bacterial growth and production. It is fair to believe that in this case the chemical substances calling forth the leucocytes are almost wholly the product of the defending tissue cells. If, however, in the example cited, the tissue cells had been so wanting in vitality as to be incapable of defense the bacterial invasion would have predominated and a degree of injury to the tissue cells resulted such as would produce death of tissue instead of calling forth the process of defense. The same result might follow an unusually virulent bacterial invasion, even though the initial vigor of the tissue cells be not impaired. In either case, if the tissue cells be overcome, gangrene instead of defensive inflammatory changes results and the production of chemotaxic substances and accordingly the calling forth of an absolute leucocytosis by the tissue cells is proportionately wanting. Such leucocytosis as is produced is to be attributed largely to the production of chemotaxic substances by the bacteria and by the active process in the zone of slight exudative inflammation at the border of the gangrenous area. Under these conditions the calling forth of an absolute leucocytosis is less marked than in an active inflammation.

This pathological picture and the expected findings as to the existence of an absolute leucocytosis in the class of cases cited are in entire agreement with clinical experience. In an active process there is a high leucocyte count in proportion to the degree of activity; in the less active gangrene the leucocytes are increased to a lesser degree. While in these cases the bacterial growth is inconsiderable, and hence their production of chemotaxic substances is probably much less than that of the tissue cells, in some processes, as for example a lobar pneumonia, we may believe that the part played by the bacteria is more considerable, proportional to the greater growth of bacteria. This, as well as the extent of tissue involvement, appears to explain the high absolute leucocytosis in such conditions.

In considering the increase in the number of leucocytes in the blood, it must not be overlooked that generally there is an accompanying increase of leucocyte formation by the blood-producing organs. Moderate temporary changes in the number of leucocytes may at times be regarded as merely a redistribution of the leucocytes of the body, but any considerable numerical increase, especially if continuing for some time, is certainly accompanied by an increased formation of these blood elements. As to the factors operative in bringing about this increased formation we have no certain knowledge. Doubtless the forces normally operative are stimulated to increased

*Read before the Medical Association of the Greater City of New York, December 16, 1907.

activity by the rapid withdrawal of the morphological products from the blood-forming organs and it is reasonable to suppose that additional stimulating action is exerted by the chemotaxic substances we have been considering.

The view here put forward, that leucocytosis is proportional to the active production of positive chemotaxic substance by the tissue cells and that it is not produced altogether or in most cases largely by the bacteria, explains some supposed failures of the absolute leucocyte count in diagnosis. It is occasionally noted that pus fails of recognition by this means. The reason is clear, when we consider that it is not the presence of pus that calls forth the leucocytes, nor is it the absorption of toxins with the accompanying fever. It is largely the formation of chemotaxic substances by the defending tissue cells, a process that is no longer operative when the active reaction of the tissues has ceased. Doubtless in these cases there was a leucocytosis during the formation of the pus; but the formation having ceased, the active defense with the formation of chemotaxic substances no longer continues and, accordingly, a leucocytosis is not produced. It will always be found that in such cases the pus is more or less of the stagnant variety. The failure of leucocytosis is not directly due to the walling in of the pus, but to the absence of active defense which the walled off product no longer arouses.

In the leucocytosis of inflammation there is not only an increase in the absolute number of leucocytes in the blood, but usually a change in the proportion of the different kinds of leucocytes, a change that ordinarily consists of a relative increase in the proportion of the polymorphonuclear variety. The existence of this relative increase may be regarded as of even greater diagnostic import than the absolute leuocytosis, particularly as its entire absence is much less frequent in cases presenting conditions which would be expected to call forth a blood reaction. It is evident, from the occurrence of the change, that the influence producing the absolute leucocytosis is exerted especially upon the polymorphonuclear variety, thus bringing about the relative increase in the circulation.

It has been suggested that the reason of the action upon these particular cells is because, since the chemotaxic substances act by diminishing the surface tension of the protoplasm of the cells, the relatively larger amount of protoplasm of the polymorphonuclear variety affords opportunity for a more marked effect. It is probable that this is a partial explanation only, and that the rapidity of formation is also a factor, though, as we have seen, this latter may result in part at least from the more rapid withdrawal of the polynuclear cells from the blood-forming organs because of the operation of the chemotaxic factor.

In considering the possible explanations of the relative leucocytosis without corresponding absolute increase, it has seemed to me that it is to be attributed to two causes. First, to a diminished rate of formation of the chemotaxic substance. The less activity of the diseased tissues in those inflammatory processes where the leucocytosis is more relative and less absolute is consistent with this view. Because of this and, probably, as well, because of a diminished physiological capacity of the blood-forming organs in the individual whose tissue reaction to injury is less responsive, there is less active leucocyte formation aroused by the condition. Hence, the rate of leucocyte formation is a second probable factor operating to determine the degree of absolute leucocytosis. Whatever the cause, the relative polymorphonuclear increase is a certain indication that there is a factor operative in bringing forth the leucocytes that is not physiological. Moreover, the greater the relative increase the more urgent the call of the diseased tissue; while, again, the less response by an absolute increase, the less is the injured tissue able to declare its needs.

Again, we find confirmation of this point of view in practice. If, for example, we are dealing with a diseased appendix and the blood shows a high relative polynuclear leucocytosis, say an increase above the high normal 72 per cent. to 82 per cent. or over, while the absolute number of leucocytes fails to show a corresponding increase, remaining, let us say below 15,000, then we may conclude that the injury to the tissue is severe and that we have tissue destruction rather than the active operation of defense which leads to the inflammatory tissue changes which culminate in the formation of pus. In other words, with these findings we would rightly diagnosticate a gangreous process rather than an active inflammatory defense.

A third change which the blood may undergo in inflammation is an increase in the amount of fibrin formed when the blood is removed from the body. This character is so marked, in certain cases, its detection so simple, and its indications so definite, that it is surprising that it is not more frequently considered. Indeed, it should form a part of every blood examination where inflamed tissue is to be given consideration.

We shall best appreciate its production and significance by considering the mode of formation of fibrin in the process of inflammation. Examination of tissues undergoing slight degrees of inflammation reveals little formation of fibrin. As the process reaches a more advanced stage fibrin formation is observed, but the maximum of the formation is reached only when we have inflamed serous surfaces, in which case the formation becomes relatively large and proportional to the extent of surface involved. In interstitial suppurative inflammation we have a process in which the exudate produced is rich in cells, but in which there is strong inhibition to the formation of fibrin.

Fibrin formation is due to the action of fibrin ferment on the fibrinogen of the blood. The fibrin ferment in turn is formed from its inactive precursor prothrombin or thrombogen by the activating action of thrombokinase which is liberated from the leucoctyes. The throwing into the circulation of thrombokinase, as a result of the dissolution of leucocytes, not only tends to produce fibrin in increased quantity at the site of the inflammatory process, but gives to the systemic blood in general the property of forming fibrin in increased amount. This fact affords the valuable diagnostic feature of the blood to which reference has been made. It is an index to the extent and degree of the formation of fibrinous exudate in the body.

This being the case, we should expect to find no increase of fibrin in slight localized inflammation or in suppuration, and much fibrin increase in inflammatory processes in which there is much formation of fibrinous exudate. As a matter of fact, this is precisely what we do find. In the early stage of inflammation and in uncomplicated suppuration the blood shows little or no fibrin increase. In acute peritonitis, acute articular rheumatism, acute meningitis, and in pneumonia during the formation of exudate the fibrin increase is most

marked and clearly indicates that the leucocytosis of these diseased conditions is not due to suppuration, unless, indeed, two processes be simultaneously occurring.

The value of this observation is not only to determine the character of the process in a given case, but also to diagnosticate changes that occur at different stages of a disease. Thus, when a localized inflammatory or suppurative process in the abdominal organs gives rise to a peritonitis, valuable indication of this fact is found in the developing hyperinosis, *i.e.* increased fibrin formation. By this observation we may oftentimes diagnosticate a developing peritonitis, thus obtaining the information that a relief of symptoms is due to the bursting of an abscess and not to the subsidence of the inflammatory process.

PART II. THE DIAGNOSTIC PREVENTION OF THE TERMINAL STAGES OF INFECTIONS OF THE APPENDIX AND GALL-BLADDER, BY

W. A. BARTLETT, M.D.

THE infections here to be considered are for convenience limited to the appendix and gall-bladder, although the conclusions drawn are in the main as well applicable to similar conditions in other organs. By the term terminal is meant the establishment of an empyematous or the extension of a gangrenous stage.

Upon observing the post-operative findings revealed in a ruptured empyematous appendix or a gall-bladder infection that has progressed to the general septic stage, we have all indulged in the useless regret that surgical aid was not invoked in time to avert this disaster. Such a regret, however, is not without purpose if it will but serve to remind the clinician that in the earlier stages of these infections there is a moment or a day in which a definite line of demarcation exists between the safe ground of a protected infection and the unsafe one of an unprotected one. This is the psychological moment for action; and that it is not taken advantage of by those in charge, implies that either terminal conditions were already established before the case came under observation, or, if the reverse, an incorrect interpretation of the associated symptoms is accountable for the urgency of the moment being unsuspected. This incorrect interpretation is due, as a rule, to the pitfall into which so many are led, through basing their diagnosis on the clinical findings alone; for while there are many instances, as we all know, where they are obviously indicative of an active infection, in as many they are not. The mildness of a symptom onset or, on the contrary, one that is severe, but exhibits a rapid decline, proving an unreliable test, on the one hand, even of the existence of an infection, or on the other, of the stage to which a recognized infection has progressed. Under such a policy, we constantly see a gall-bladder or appendix infection progressing to its terminals before the attendant is aware of the process with which he has been dealing, a confusing symptomatology and diagnostic indifference or ineptitude being the responsible controlling factors.

The first and most important essential to the successful conduct of these perplexing cases, then, is that the clinician should promptly determine whether the presenting symptoms are due to an active infection in either of these structures, and, if so, to differentiate its probable stage and progressiveness. With the atypical and variable characteristics of the symptoms in mind, he would indeed be reduced to the dangerous expedient of awaiting developments, if the decision of this point depended on the clinical findings solely. Fortunately it does not, as the experience of the past few years, in which the blood reactions of inflammation have been studied, justifies the clinician in looking to them for the aid he is seeking.

As an essential factor in the diagnosis of these cases, then, an hematological examination should be made immediately, coincidently with the routine physical examination of the crucial regions in the vault and floor of the abdomen. Upon these findings, respectively, with the pulse and temperature verifications, the expediency or the inexpediency of immediate operation can as a rule be safely arbitrated. With these essentials at the clinician's command, the ultimate outcome will depend upon his readiness to employ them in time, and with such frequency as the exigencies of the situation demand; which brings us to the second factor essential to the prevention of terminal conditions. This is, that the utmost promptitude should be observed in applying the diagnostic technique above stated, when confronted by any symptom group that might be associated with an abdominal infection, no manifestation being too trivial, but it deserves the full battery of the diagnostician's technique, as, until proven otherwise, this may be the danger signal, indicating an impending terminal stage. The involved structures having been so impaired by previous infections that they are no longer able to resist an additional bacterial invasion, and a destruction of tissue integrity being then imminent, the psychological moment for surgical intervention previously referred to is at hand, as it may just precede or be associated with this breakdown.

Coming now to the practical application of this technique in the diagnosis of these infections, the citation of a few experiences will, it is believed, best serve this purpose. Only those fairly typical of the infections in question have been selected, and in these, as well, the diagnostic availability of the blood reactions will be defined. Before proceeding to these considerations, however, it will be necessary to state that from the clinician's standpoint, and for working purposes, the writer's experience justifies the grouping of cases in which the blood analysis is a diagnostic factor, into the following arbitrary classification:

1. As a confirmatory diagnostic factor, to be viewed only in a corroborative sense, where the diagnosis of a terminal condition is made on the clinical findings alone.

2. As a diagnostic factor of decisive import in aiding the clinician to correctly interpret symptoms, otherwise of doubtful meaning, or to strengthen a diagnosis already made.

3. As the determining factor, enabling the clinician to diagnose an infection in its initial stages which the presenting symptoms fail to indicate.

Under the first heading are grouped only the obvious terminal stages of infections, diagnosed by the findings of a physical examination with the pulse and temperature verifications. The blood, then, is usually not relied upon as a diagnostic factor other than in a confirmatory sense. The conditions with which such analyses are associated are typically illustrative of how not to prevent such conditions. These are the botched cases, the victims of their own indifference, or of diagnostic ineptitude; and in the first can be seen how an active appendix infection advances to its terminal stage unrecognized, by the simple method of omitting any examination, blood, physical, or otherwise, the con-

ventionality of a presenting symptomatology being regarded as a test of its insignificance, and the case then being left to take care of itself.

The symptom which prompted the patient to seek medical aid comprised a middle of the night attack of vomiting and diarrhea accompanied by some pain. His illness was attributed to biliousness. Satisfied with a cursory examination, the patient was dismissed, so far as medical supervision was concerned, with the advice for him to report if necessary. He did not, for besides feeling a trifle done up, there seemed to be no reason to consult his medical adviser again. Several days later he attributed a general muscular soreness, more noticeable in the right lumbar region, to gout and proceeded, as had been his custom under such circumstances, to knock it out by rowing, sometimes covering ten miles in one spin. This failed of its purpose, as the soreness in the right lumbar region steadily increased in severity, accompanied at times by belly pain. Two weeks from the date of his bilious attack he consulted the writer.

It was found that he had a temperature of 103° and a well-defined tender mass in the right hypochondriac region. The condition was perfectly obvious, a diagnosis of a thus far walled-in appendix empyema being made on the clinical findings and an almost negative blood reaction. Appendectomy was accepted and the condition found to be as above described.

The second obvious terminal condition unrecognized in its early stages is illustrated in a gall-bladder infection, in which the operative findings revealed numerous calculi in the gall-bladder, a chronic pericholecystitis and adhesive bands embedding the gall-bladder and extending to the stomach and adjacent colon. Behind and to the right there was a small pocket of pus. The early symptoms of the infection were some gastric distress and abdominal distention. These were regarded as of trivial import at the time, and the case was dismissed without blood, physical, or other examination. The symptoms of the subsequently slowly progressing infection comprised during a period of several months two attacks of colic and vomiting, and in the interval vague gastric distress. For five weeks previous to observation there was languor, without any acute episodes. Upon a recurrence of the gastric discomfort, accompanied by a slight afternoon temperature, the patient came under observation. The physical examination revealed the presence of calculi, and an apparently thickened and tender gall-bladder. There were no additional manifestations during the ten days intervening before operation. Repeated blood examinations revealed only a moderate hyperinosis without either absolute or relative leucocytosis.

The absence of leucocytosis is consistent with the quiescent condition of the pocketed pus, there being no evidence of inflammatory defense. The increased fibrin formation indicated the formation of some fibrinous exudate, and it is fair to presume that this was a continuation of the process around the gall-bladder.

In both of these cases, the blood findings were strikingly negative, an indication that terminal conditions were already established, and that the inflammatory processes were relatively inactive. They emphasize that the blood findings are diagnostic of a process and not of an established condition.

Under the second classification, in which we find the blood findings of decisive import, two illustrations have been selected, of rapidly advancing appendix infections that were seen at the moment of a symptom declaration. This is the psychological moment above referred to. In the first instance, severe paroxysmal pain in the abdomen and vomiting were the presenting symptoms. This began in the epigastrium and transcribed the classic angle to the right, then down to the appendix region. He "knows what it is," as this is one of many attacks. Pulse and temperature being normal, and the abdomen only moderately sensitive over gall-bladder and appendix regions, the colon was flushed and developments awaited. He grew more comfortable as the day passed, and there was no further vomiting or pain, the pulse and temperature remaining normal. On the second day, although comfortable, there was some rigidity of the right rectus muscle and increased appendix sensitiveness, the pulse being 90 and the temperature 100.2°. Surgical intervention was then tentatively considered, pending further developments. A third day of comparative comfort with no vomiting spell, pulse and temperature record unchanged, and the appendix region less sensitive, seemed again to justify deferring operation. An endorsement of this attitude was found on the fourth day's record, for, although there was still a slight afternoon fever, other symptoms were absent and the patient was hungry and out of bed. The surgical possibilities were then brought to a square issue, as he announced his intention of going to business the following day. On his past record and the acute onset, however, the writer stood firm in condemnation of such a course of action, and for the purpose of still further strengthening his position a blood specimen was taken—three days too late. The findings revealed a far more urgent situation than was suspected, as the marked fibrin formation and the pathological leucocytosis of 19,000 whites and 79.4 per cent. polynuclears justified a hematological diagnosis of an active process with the involvement of the peritoneal surface. Operation was then insisted upon immediately, but it took twenty-four more valuable hours for diagnostic conviction to have its way.

A comparative transcript of his hospital entrance examination and his operative record will possibly justify the antithetical position occupied by doctor and patient in regard to the subject matter of dispute. The former states that the patient's pulse and temperature are normal, that there is no abdominal rigidity, no tenderness other than slight sensitiveness over McBurney's point. No pain. Diagnosis, acute catarrhal appendicitis. The operative findings were as follows: Advancing peritonitis, the appendix being gangrenous at its proximal end; on section abundant purulent exudate is found, the mucous membrane being entirely destroyed, and much of the wall being gangrenous. Recurrent wound infections, prolonged convalescence and subsequent hernia probably were, as is often the case, the consequences of delay.

In the second illustration, however, diagnostic perspicacity was more in evidence, with, in consequence, better results, as will be seen. The blood in this instance was taken immediately on presentation of the case, and was the first finding to confirm a mere suspicion of an active process in a man who had had a night of nausea, diarrhea, and colic. Of indulgent habits, these symptoms seemed conventional resulting episodes, but he looked ill, so he was put through the usual routine examination. Deep appendix pressure elicited complaint only at the crest of the ilium. He had no pain, and the pulse and temperature being normal, he was permitted to go

down town, but it was insisted that he be seen at his home at 5 P.M. In the meantime the blood established the significant diagnosis of "reactions of inflammation, quite likely suppurative," based on an absolute count of 15,000 leucocytes and a relative polynuclear increase of 89.4 per cent., with a slight increase in fibrin foundation. In view of this, reflex abdominal symptoms signalized something more definite than indulgent habits. At 5 P.M. he was again examined. There being no abdominal distention the appendix region could be easily manipulated. There was little actual appendix sensitiveness. Deep pressure, however, aroused the not infrequent epigastric reflex pain. The only symptoms he had noticed during the day were some indisposition to stand straight, some pain in the back and right abdomen, and anorexia. With a normal pulse and temperature of only 100°, clinically speaking, there seemed to be no cause for urgency, except for the blood findings. Further action was postponed until the following morning. When seen at 7 A.M. it was found that though he had had a restless night, he now felt better, was hungry, and could now stand straight without discomfort and no pain. The not infrequent clinical picture now presented was that, although there was an improvement in the subjective symptoms, the symptomatic essentials of an advancing infection prevailed, to wit: A slightly increased cecal tenderness, a marked abdominal reflex, when the abdomen is tapped over the appendix, and a blood reaction which, while not differing in its polynuclear proportions from the previous one, showed now a more marked fibrin increase. These findings were deemed sufficient, although the pulse and temperature remained as before, to justify immediate operation. The usual struggle between diagnostic conviction and antioperative prejudice had to be fought out, and it took three hours to finish it, as the elusive improvement in the patient's feelings were not to be swept aside by the asserted revelations of a drop of blood and the, to him, unintelligible manipulation of his abdomen. Meanwhile, time, that was of vital import in securing an uninfected wound, was passing. How important this is, the operative findings will show, as, upon reaching the appendix, a small amount of bloody serum exudes from around its base, where there is a small area of gangrene. The adjacent peritoneum has, however, thus far escaped infection. On section the lumen shows an abundant purulent exudate. Primary union was secured.

In both of these illustrations the absolute and relative leucocytosis showed an active process; a condition in accord with the clinical and abundantly confirmed by the operative findings. In both cases the degree of hyperinosis was of material import, indicating, in the first instance, the inflammatory involvement of the peritoneum, and in the second, a process extending in the same direction and which prompt operative interference enabled us to prevent.

Under the third classification is demonstrated the availability of the blood reaction in the diagnosis of the initial stages of an appendix infection.

These are the cases referred to in the foregoing remarks, where the necessity of a routine blood count is especially emphasized, as without these reactions the symptoms could easily be misinterpreted and the case in consequence be dismissed as of trivial import. A number of these manifestations can in this way occur without arousing a suspicion of the underlying cause. The prevention of the possible terminal outcome of such cases, perhaps months later, is in the clinician's hands, if the infection is thus early diagnosed, and the patient is willing to accept an operation solely as a preventive of what to him is only a possibility.

Of a number, the following has been selected, as an instance of an appendix affection where both of these conditions were complied with. The symptoms in this case were anorexia, gas eructation, and marked abdominal distention. There being no previous history of an appendix infection, and the clinical and physical findings being negative, this disturbance was attributed to a colon impaction, as he had been obstinately constipated. The routine blood count unexpectedly indicated a definite lesion, "reactions of inflammation, quite likely suppurative," being revealed by an absolute 16,000 and relative 89 per cent. leucocytosis and a moderate hyperinosis. In view of this, the gas attack assumed a different aspect. Although the gastric and intestinal reflexes ceased in forty-eight hours, for precautionary reasons the blood count was taken daily for the succeeding week. During this period there was not a symptom of the infection which the blood reactions continued to give evidence of. In the last count, however, as the hyperinosis had disappeared and the pathological leucocytosis was apparently less, the infection was not regarded at the moment as being of a progressive character. The patient's business obligations making it impossible for him to secure prompt attention in the event of an emergency, being a salesman, and appreciating the consequences of being caught en route, he readily submitted to an "interval" operation, the so-called quiescent characteristics of which are revealed in the findings as follows:

The appendix is much thickened and engorged and is surrounded by recent and old adhesions. Its lumen is filled with cheesy material. Microscopically, the effects of the recent acute process are disclosed in the thickened blood-vessels, the marked increase in submucous connective tissue, and the periglandular infiltration in which eosinophilic pus cells predominate.

The outcome of such conditions is of course problematical, whether of a terminal or involution character, but in view of the probability of its being in favor of the former it was fortunate that the symptoms were correctly interpreted, as otherwise this case might easily have been added to the number of sudden terminal emergencies which it is our duty to prevent. From the writer's standpoint, the necessity for an early operation in such cases as the above is not open to question.

STRICTURE OF THE EUSTACHIAN TUBE WITH ITS BANEFUL CONSEQUENCES TRACED TO ADHESIONS IN THE FOSSA OF ROSENMULLER.

By W. SOHIER BRYANT, A.M., M.D.

NEW YORK

While Assistant in Anatomy and Otology in the Harvard Medical School during the ten years from 1887 to 1897, I had the privilege of examining all the anatomical material there, and noted that in almost all adult subjects the fossæ of Rosenmüller were more or less obstructed. This obstruction was due sometimes to lymphoid and at other times to fibrous tissue. Of the former, the younger subjects had the greatest amount. The elder ones had less, and the aged had none at all. With increasing

age, then, it appears that the lymphoid tissue atrophies and leaves only fibrous tissue adhesions. Most of the fossæ examined were lined with a layer of lymphoid tissue, which was thickest on the posterior wall. The lymphoid obstructions in the fossæ were seen to originate from hypertrophy of the

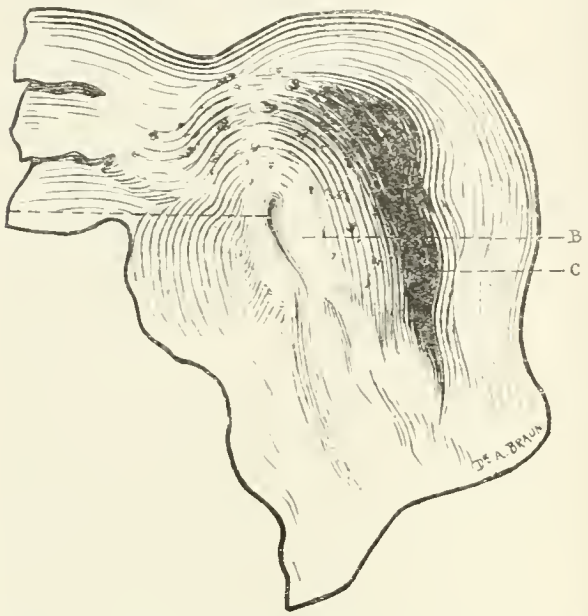

FIG. 1.—A normal right Eustachian tube and fossa of Rosenmuller.

lymphoid lining which either obliterated the fossæ to a greater or lesses degree or bridged them over. The obliteration, whether partial or total, was caused either by filling the fossa from the fundus or by adhesions between the anterior and posterior surfaces across an abnormally narrow fossa. These adhesions varied greatly in friability; some could be broken down easily with the fingers; others resisted all efforts at rupture. Their location also varied, but, on the whole, they were most abundant either at the fundus of the fossa or at the superior commissure. As before stated, at a more advanced age, with the disappearance of the lymphoid adhesions, the fibrous tissue connections alone are left. These may vary in density from a very fragile thread to a thick band of almost tendinous rigidity. They may occur anywhere, but are most abundant at the upper commissure. The fibrous tissue adhesions may form a cribriform network or they may exist as distinct bands which are apt to run from the tubal side upward and backward, less often downward and backward. Syphilitic, diphtheritic, or other ulcerations rarely cause obliterating cicatrices in these fossæ.

Though the presence of these adherent bands in the fossa of Rosenmüller had been noted by me for the last twenty years, their clinical significance did not become known to me until three years ago. At that time the use of the salpingoscope made clear to my mind the relationship which these obstructions bear to the function of the Eustachian tube. The presence of a large quantity of lymphoid tissue in the fossa is often associated with changes in the middle ear similar to those occurring in extensive lymphoid hypertrophy of the nasopharnyx. They are due to manumetric and drainage disturbances resulting in congestion, infection, and later atrophy. The pathological condition found in the middle ear when fibrous bands form in the fossa of Rosenmüller is usually of the kind classified under otitis media catarrhalis chronica.

The mass of lymphoid tissue in the fossa tends to imperfect patency of the Eustachian tube, thus preventing normal drainage and ventilation of the middle ear. This is due to the impossibility of properly opening the tube when the fossa is filled, since the mass interferes with the backward motion of the cartilage necessary for physiological opening of the tube.* The result is the same as if a mass of adenoids in the nasopharynx caused obstruction of the tube. There is always a slight amount of opening as a result of the stiffening and retraction of the anterior and membranous wall of the tube due to contractions of the tensor palati muscle; but this is not sufficient to produce a free tube in these cases, especially when there is much swelling of the lining membrane of the tube.

The fibrous tissue connections also lead to closure of the tube, but only indirectly. In this case, contraction of the fibrous bands pulls the cartilage from its normal position backward toward the posterior wall of the fossa, thus preventing the normal closure of the tube. This position of extension is necessarily constant, because there is not a sufficiently strong muscular apparatus for closing the tube. Since the tube is held open in this way, the normal apposition of its anterior and posterior inner surfaces does not occur, as it naturally would during rest. Consequently the lining of the tube becomes engorged by venous and lymphatic congestion, which results in the closure of the tube, not at the pharyngeal orifice, but at a slight distance from it. The salpingoscope shows us the obstruction in the fossa and the tubal cartilage approaching abnormally near the posterior pharyngeal wall. The pharyngeal mouth of the tube appears to have the triangular conformation of the normal open tube instead of the slit-like form characteristic of the normal orifice when at rest. However, there is this difference: The lumen of the normal open tube appears to extend well beyond the range of vision;

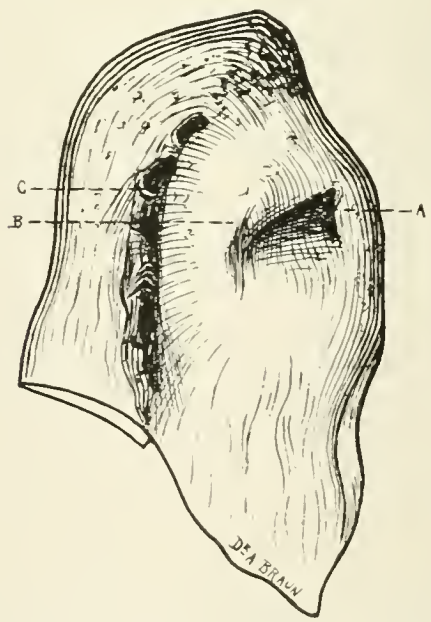

FIG. 2.—The left Eustachian tube held open at its mouth by the bands of adhesions in the fossa of Rosenmuller. The tube is closed by collapse of its walls at a short distance from the pharyngeal orifice.

while in this abnormal condition the lumen extends but a short distance inwards, and is obstructed by the apposition of the mucous membrane lining.

This closure of the tube, which has for a number

*Sohier Bryant: "The Eustachian Tube, Its Anatomy and Its Movements," etc. MEDICAL RECORD, Vol. 71, No. 23, p. 931, June, 1907.

of years been called stricture of the Eustachian tube, is followed by all of the evils, both pneumatic, trophic, and infectious which occur in a middle ear shut off by a chronically closed tube. The results of tubal stricture are well recognized. They comprise the most obstinate forms of middle-ear catarrh with tinnitus, deafness, and the multitude of disagreeable symptoms dependent upon the changes in the middle ear. The tubal stricture, moreover, is one of the most, if not the most important factor in determining middle-ear infections and the severity of their course. Middle-ear infections rarely go on to suppuration when the tube is patent, and they do not cause mastoiditis or any of the dangerous complications following osteitis of the mastoid process.

Diagnosis.—Either the finger or the salpingoscope can be used to make the diagnosis. The latter, however, is preferable, since it will show how much the movement of the tube or its normal lumen are interfered with. The tube should be watched while the patient swallows, and the movements of

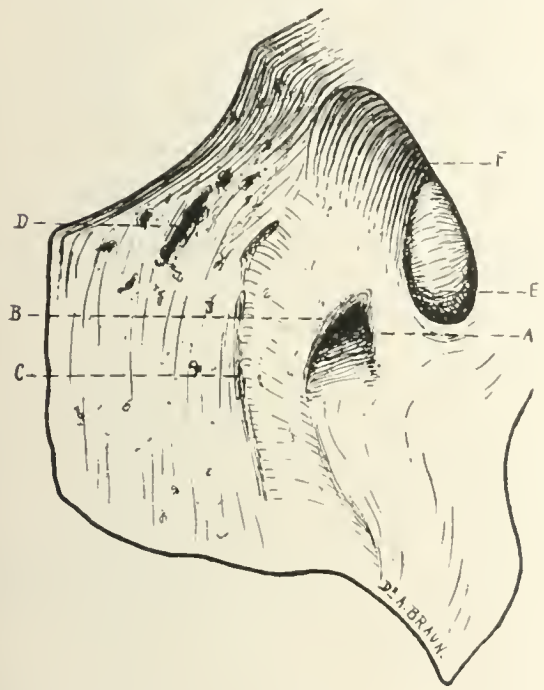

FIG. 3.—The pharyngeal mouth of the left tube held open by the obliteration of the fossa of Rosenmüller; A, pharyngeal ostium of Eustachian tube; B, torus tubæ Eustachii; C, fossa of Rosenmüller; D, pharyngeal bursa; E, posterior end of lower turbinal; F, nasal septum.

the cartilage scrutinized to see if there is any impediment in the fossa of Rosenmüller.

Treatment.—Early treatment of the obstruction of the fossæ is indicated as soon as the diagnosis is made. The disturbances in the middle ear, which are caused by the pathological conditions in the fossæ will then yield more readily to appropriate treatment. The results are infinitely more satisfactory than when the fossa is neglected altogether, since an amelioration of the aural condition invariably follows restoration of the function of the tubal mouth and fossa of Rosenmüller. The preliminary treatment of the middle ear condition consists in removing with the curette any lymphoid tissue present. The adhesions which obstruct the fossa must be broken down. The more delicate fibers readily give way to the fingers; the more resistant ones can sometimes be torn with the finger, but occasionally they are so dense that cutting is necessary. Often this process of rupturing adhesions whether done with the finger or with the knife, must be repeated a number of times, and silver nitrate applied until the mucous membrane has healed and is free from adhesions.

Conclusions.—(1) The fossæ of Rosenmüller are subject to obstructions and adhesions which interfere with the physiological action of the Eustachian tube through imperfect movements of the tubal cartilage, resulting in stricture of the Eustachian tube.

(2) This can de demonstrated by the use of a salpingoscope.

(3) Relief from this impediment allows of more effective treatment of the middle-ear condition.

THE ORGANIC FACTOR IN HIGH BLOOD PRESSURE.

BY ALEXANDER HAIG, M.A., M.D., OXON.

LONDON.

IN Volume 89 of the Transactions of the Royal Medical and Chirurgical Society there is a paper of mine on "Capillary Circulation and Blood Pressure and the Conditions that Control Them." In my reply on the discussion of this paper I point out, as I had already done in previous writings, that nothing which I claim for the influence of uric acid on capillary circulation and blood pressure is to be taken as excluding the undoubted power of the nerves to contract the arterioles and thus aid in raising blood pressure.

My position has always been this: Uric acid has a great effect on capillary circulation and blood pressure* and it is a factor which it is comparatively easy to control either by diet or by drugs. Let us do what we can to control it and see what is left. I also pointed out that to some extent it is possible to distinguish between the blood pressure which is due to obstruction of capillaries by uric acid and that caused by irritation of a sensory nerve.

My attention was directed to this point some years ago by observing that a patient, who had a gastric ulcer, which had produced a slight hematemesis and a rise of temperature, had a blood pressure out of its normal relation to the capillary reflux.† The capillary reflux was somewhat quick, owing to the rise of temperature, so that looking to the reflux alone I should have expected a normal or subnormal blood pressure. But the pressure was raised to 140, and rose a little above this with an increase of abdominal pain. Here we had clearly to deal with the result of irritation of a visceral nerve, and the blood pressure did not bear its usual relation to the rate of the capillary reflux. I have seen the same thing in other conditions of local pain, *e. g.* that met with in connection with the nerves of the teeth.

I believe then that local lesions, especially those of the abdominal viscera, do produce a rise of blood pressure by contraction of the arterioles, and that a further rise of blood pressure is produced over and above this by excess of uric acid obstructing the capillaries.

In lead colic, for instance, we may have both these causes in action, visceral pain and excess of uric acid in the blood as a result of the dyspepsia. And

*I have suggested that it blocks the capillaries, others suggest that it contracts the arterioles; this does not at present concern us.

†The rule is capillary reflex × 20 = corresponding blood pressure: *e.g.* C. R. 5-6 (half seconds) = B. P. 100-120 mm. of Hg. (C. R. calculated in ½ seconds of time and B. P. in mm. of mercury.)

the same may hold in quite a number of other troubles, the part due to uric acid being removable, the organic factor being sometimes removable as in lead colic, in other cases (*e. g.* chronic irritation, ulceration, or adhesions between abdominal viscera) not removable.

If the organic factor is due to the local irritation of uric acid then it is removable, at least in part, but if it is an old scar in joints, heart, or abdominal viscera then it may not be removable and a complete reduction of blood pressure may not be possible.

Even here, however, uric acid removal may cause much improvement, as every old scar is irritated by it, if complete cure is impossible.

I am in the habit of telling patients that they must not expect miracles, that diet will not remove a lamp post or a five-barred gate, but that it can be tried without danger if they can take proper quantities of food, and then the result will show how much was organic and how much functional.

The great characteristic of the headache and depression that are due to uric acid is that they are periodic, and between times blood pressure may be quite normal. When any of these troubles are chronic and continuous there is probably an important organic factor.

As to periodic headache, it is generally relieved by diet, and the blood pressure is reduced to a considerable extent, often to normal, except for one or two days in a year, and the same applies to periodic depression. Thus a patient in middle life suffering from mental depression has been several years on diet and considers himself cured, his blood pressure is lower than it was but is still often 10 to 20 above normal; possibly there is an organic factor still left in him (*e. g.* gastric or abdominal irritation of some kind such as an old ulcer adhesion or scar might produce).

Still uric acid and uric acid alone will apparently produce very high blood pressure, *e. g.* that of Bright's disease, which can often be reduced to nearly normal in a few weeks, with a corresponding quickening of the capillary reflux and a clearing of uric acid out of the blood and urine, and all these things go together; no one can be produced without the others. If the blood is not cleared of uric acid the reflux does not quicken and the pressure does not fall.

But, if it gets time to act, diet does the same thing, only more gradually, as one would expect; the quantity of uric acid in the blood is slowly reduced and all the other things altered in proportion.

Again there can hardly be any room for doubt that the diurnal fluctuations of blood pressure are due to uric acid, for they are to be met with both in physiology and pathology, and in both they are to a large extent controllable by measures affecting uric acid, so much so that they can often be made to vary in either direction at pleasure.

Even if we have to deal with a definite organic factor, *e. g.* a gastric ulcer or an abdominal adhesion, there is no reason why this should produce less effect in the evening and more in the morning when digestive function and activity are common to both times. If, say, the organic lesion accounts for a blood pressure of 130 this may be increased to 150 in the morning with more uric acid and diminished to 130 or 140 in the evening with less.

Again, as I have before said, if the phenomena of Raynaud's disease are due to contraction of arterioles it is difficult to believe that any arterioles can remain contracted until the part passes into gangrene. If, however, the stoppage of circulation is due to uric acid mechanically blocking the capillaries, there will of necessity be more and more colloid uric acid thrown out as the circulation slackens and the part becomes cold. This action of cold as a precipitant of uric acid will also account for the limitation of Raynaud's disease to surfaces and extremities.

It is quite common for those who suffer from chilblains to get free from them, even after twelve months on diet, and if they at any time take uric-acid-bearing foods again, the chilblains are among the first things to return.

It seems to me, then, that the organic factor cannot possibly account for all the phenomena, nor does it in any way account for the influence of drugs on the one hand or of diet on the other; for the only factor common to both these is their influence on the quantity of uric acid in the blood and tissues. Everything that clears the blood of uric acid produces one effect, everything that floods it with uric acid produces the other: *e. g.* a salicylate will at any time alter a reflux from 5 to 8. There is no doubt that diet has cured such periodic troubles in hundreds and hundreds of cases, yet this effect is more certain and the result more complete in the young before definite visceral lesions are produced; but even some of these lesions (*e. g.* in joints, heart, and abdominal viscera) may apparently be diminished, and the irritation in them reduced, as the diet is continued year after year.

The conclusion is, I think, that high blood pressure may be due to uric acid or to an organic factor or to both in varying proportions. In all cases (if there is time) the uric acid factor is removable; and the organic factor, if due to uric acid, is also to some extent removable.

The capillary reflux and the blood pressure alter from day to day and hour to hour with the amount of uric acid passing through the blood; but there are undoubtedly other factors which influence blood pressure, and these may or may not be altered by treating uric acid.

By acting on these indications we can in many cases get an answer to important problems affecting the causation of circulation diseases. I should never claim anything as the effect of uric acid which diet will neither prevent nor cure.

7 Brook Street, Hanover Square.

INCIPIENCY IN TUBERCULOSIS FROM THE STANDPOINT OF SANATORIA.

THE SAFETY AND THE VALUE OF THE TUBERCULIN TEST WHEN SAFEGUARDED SOLELY BY THE CLINICAL METHOD.

By HENRY B. DUNHAM, M.D.,

GLEN GARDNER, N. J.

RECENTLY PHYSICIAN MASSACHUSETTS STATE SANATORIUM; ASSISTANT CHIEF PHYSICIAN NEW JERSEY SANATORIUM FOR TUBERCULOUS DISEASES.

The prevalence of tuberculosis and the Profession's ignorance of its commencement in almost all the cases that occur can be shown best by citing statistics from States having sanatoria. There are, presumably, as many as 15,000 cases of tuberculosis in Massachusetts. In the reports received by the investigating Commission,[1] 7,779 consumptives were positively accounted for within the State, but if these were all, then less than half of those afflicted would survive a year, as the latest death-rate is 4,702.[2] It would be impossible to determine how many more than 4,702 cases originate each year in

Massachusetts, but that many are required to supply the annual deaths at home. Those who may die in other States and climates and those who recover either at home or abroad, are not included in the above estimate of those who contract the disease in a single State. Among the 7,779 consumptives who were reported to the Commission, 2,792 were designated by physicians as "slightly ill" and "feeling able to work."

With conditions existing as stated, does it not seem strange that a State institution, accommodating 350 patients, upon which the people gladly expend vast sums to assist it in effecting recoveries should barely be able to fill one-third of its beds with slightly affected cases?

At the Massachusetts State Sanatorium 75 per cent. of the patients with incipient disease recover, and they rarely relapse. Is it not unfortunate that circumstances should cause 400 of those who develop the disease every month, to ignore absolutely, or invariably until too late, such an available means of treatment, especially as no other treatment is undertaken which suffices to prevent a fatal termination?

The reduction in the death-rate from tuberculosis since 1881 has been continuous, but thousands of lives are still lost yearly. If a special effort should be made by physicians, might not the disease be detected and receive treatment in its incipiency in perhaps one-sixth of the, at present fatal, cases? If this were done Massachusetts could care for its proportion of cases with its present equipment.

No State sanatorium has as yet been furnished with incipient tuberculosis to its full capacity, and the curable cases take precedence over all others seeking admission. Eighteen States will have sanatoria in 1908, and patients with incipient tuberculosis will be required that these institutions may accomplish their highest end.

At present every State sanatorium is in advance of the willingness or ability of both the people and the profession to supply it with incipient tuberculosis. The superintendent of the Rhode Island Sanatorium deplores this state of affairs as follows:[3] "If the number of curable cases which a sanatorium receives is small, its usefulness is correspondingly limited, and our professional pride should not allow the willingness of the State to finance the treatment of curable cases to surpass our ability to furnish the cases."

The willingness of the State has nevertheless surpassed the ability of the profession in Massachusetts, New York and Rhode Island since the erection of their respective sanatoria. The superintendent of the New York institution makes this statement in his official report:[4]

"As a result of two and one-half years' actual experience at this hospital, I find that incipient disease is practically unknown to the profession save to those actually engaged in special work along this line."

The number of new cases of Tuberculosis Pulmonalis reported December 7, 1907, to the Sanitary Bureau, Health Department, New York City, was over double that of the deaths occurring in the same week.

As in New York State 14,000 deaths occur annually from consumption, it may be assumed that twice 14,000 patients could be reported as contracting the disease in the same time; nevertheless, fifty beds (out of a total of only two hundred) remain empty at the State Hospital, Raybrook, because it is impossible to obtain that number of patients with incipient disease.

In the New Jersey Sanatorium, at the present writing, less than 13 per cent. of the patients have incipient disease, the average duration of symptoms is reckoned in years, many have marked febrility with advanced processes, and a few, in addition, ulcerated larynges.

These apparently were the best obtainable cases, with inability to pay constituting not the slightest bar to admission. Each applicant has to be certified by his examiner, as having "tuberculous disease of a curable nature." There are more official examiners in New Jersey than in other States having sanatoria, and 66 per cent. of all applicants so far have been accepted. About 45 per cent. are taken in Massachusetts, while in New York, at the Department of Health Clinic, 16 per cent. were accepted, and in Buffalo the examiner, Dr. Pryor, recommended only abut 7 per cent. of those applying for Raybrook.[4]

In Rhode Island,[3] 50.9 per cent. of about two hundred consecutive cases admitted to their institution had delayed an average of 7.9 months after the onset of symptoms before consulting a physician, most of the remainder, or 46 per cent., had consulted a physician some time after the symptoms had been in progress two months, received an incorrect diagnosis, and, as a result, waited an average of 11.3 months before the presence of tuberculosis was established and proper treatment prescribed. The results of treatment, as might be expected, were more unfavorable with the latter set. From these statistics of Dr. Barnes we can deduct the following charitable conclusions: A patient, suspected of having tuberculosis, who is put off until "another time" will probably have too well marked disease when the evidence, not at first eagerly sought, pronounces itself. A person with tuberculosis who thinks he has been passed upon as sound, will cling to that impression for months after the individual without that impression has become quite certain of the character of his symptoms.

The patient with tuberculosis is greatly to be blamed for not early seeking medical advice: but when physicians are actually confronted with the opportunity, they often fail to make an early diagnosis of tuberculosis. Why is this? The literature pointing out the way is voluminous, and I am not referring to some subtle "pre-tuberculous" state; nor do the reports of professional inadequacy quoted owe their existence to the specialists' too exalted viewpoint in regard to incipiency; on the contrary, ordinary sanatorium incipient cases can be diagnosed in the majority of instances merely by careful attention to the history and symptoms of the patients, as described by Otis.[5] *Anything abnormal* in the apex of a lung is of itself enough to warrant a tentative diagnosis which can be definitely settled by tuberculin, preferably after the patient has started treatment. The type of "incipient" tuberculosis which is received for treatment at Rutland can be diagnosed in 66 per cent. of the cases without recourse to other data than that derived from examinations of the sputum.

This statement is not intended to encourage too long delays for a positive report on sputum, but is made chiefly to show clearly that, in seeking patients in the "incipient" stage, sanatoria are not asking physicians to draw unduly upon their imagination, nor to decide recommendations offhand upon general principles.

At Rutland, the diagnostic use of tuberculin has been found to be a requisite in the establishment of a positive diagnosis in less than one-sixth of the cases there classified as incipient. That sanatoria

should receive a greater number of cases in which the resort to tuberculin becomes a more common necessity, is beyond refutation. Tuberculin as a diagnostic agent should also be more generally employed. Before coming out, however, too strongly on this aspect of remedial possibilities, let us not forget that nearly five thousand doomed to die yearly of tuberculosis in a model State, like Massachusetts, certainly receive no diagnosis which exerts a nullifying influence upon that ultimate result; when at this stage of medical progress it might be expected that without assistance from tuberculin a large number of these victims should have had their disease known by its symptoms and under treatment early enough to effect a material reduction in the quoted death rate. It is certainly true that our opportunities for successful treatment exceed our capacity for complying with the treatment's conditions of success.

If general practitioners and specialists of all branches of medicine everywhere, could only develop an alertness to tuberculosis which is the prime requisite for the intelligent use of tuberculin, then indeed the State and perhaps the National government might be taxed to its utmost in an endeavor to keep pace with the profession and its auxiliaries.

The sanatorium might then be succeeded by influential employment bureaus which could, for instance, among other things entailing no further expense, doubtless make the present Rural Free Delivery System add much to its sphere of usefulness.

Let us hasten the time when tuberculin will become a more commonly used agent in diagnosis. The diagnosis of tuberculosis by means of tuberculin is becoming more than ever available to the general practitioner. Calmette's method,[6] through application of the opthalmo-reaction, furnishes what has long been needed, a simple and readily available test which, even if not absolutely conclusive in every case, can prepare the way for more exhaustive measures when the results with it are negative.

One drop of a 1 per cent. solution, or less at first, of purified tuberculin (Tuberculin precipitatum) is instilled into the conjunctival sac of the patient's eye. If the patient is tuberculous, a decided congestion and a watery and serofibrinous exudate occurs between three and twenty-four hours later. The larger experience of others as well as a few tests of my own have given almost uniformly positive results in cases of definite tuberculosis, and without reactions occurring in the presumably well. The percentage of error is probably a little more than with tuberculin used hypodermically. Until the experience with it covers very many more cases than at present, it would be wise to use tuberculin in the usual manner after all negative instillations, when the symptoms still point to the possible existence of the disease. When this is done the initial dose injected need not be as small as would otherwise be deemed advisable. Opportunities for inaccuracy and carelessness in the hypodermic method of administration are plentiful, but not more so than with many, now familiar, painstaking medical accomplishments. When properly administered tuberculin is a thoroughly reliable means of obtaining evidence of tuberculosis and when cases are selected carefully it is perfectly harmless. A report of my experience with it at Rutland should serve to strengthen this statement and also be a step toward answering questions which have some bearing upon the practical use of this valuable diagnostic aid. During the past year the great impetus to tuberculin therapy given by Trudeau has been shared somewhat by the same agent applied diagnosticaliy. There is no doubt but that those who formerly opposed its use did so largely owing to the "difficulty of obtaining a reliable product,"[7] or because "unconvinced of its innocuousness."[8] An increasing demand and added experience have practically done away with the first objection, and its successful use in the therapeutic field has helped to do away with the second.

With many earlier writers[9] on the diagnostic use of tuberculin, there was a prevalent opinion that the tolerance produced by very small repeated injections interfered with its reacting qualities and that a reaction might be absent or not nearly as distinct and decisive as when only a few larger size doses were administered. The dosage which is at present recommended and satisfactorily employed by almost all observers[10] at the commencement is very small. A fraction of a milligram which is often cautiously repeated[11] before an increased dose is injected. That a tolerance to tuberculin is nevertheless easily established is a fact familiar to all, as it is upon this possibility that its therapeutic use depends.

It will now seem paradoxical to state that tuberculin has a marked cumulative property,[12] and that this sometimes even shows itself suddenly when it is being administered for the purpose of immunization, as in the hypersensitive cases described by Trudeau.[13] It is a well-known fact that the same dose of tuberculin which has been found insufficient at first to produce a reaction, when repeated may cause a marked reaction.

It would be well if we could always tell in the diagnostic administration just when and at what point the cumulative tendency ceases and tolerance begins. Theoretically it is the overlapping of negative phases which constitutes the cumulative effect and if it were always possible to obtain easily a correct opsonic index to tubercle bacilli, the border line between these opposite effects of tuberculin could doubtless be drawn in all cases. Opsonic work requires much time, and as there seems to be a doubt as to the possibility of complete accuracy[14] with this particular subdivision of opsonic work as at present developed, interest must still cling to the clinical method[15] in all tuberculin administration.

In order to give an idea of what can be accomplished by clinical methods in the selection of cases suitable for receiving large doses of tuberculin, the following experience with tuberculin in the earlier cases at the Massachusetts State Sanatorium is given. The incentive for painstaking care in the selection of these patients can be best understood by stating that each patient received but one dose of tuberculin and that dose was 10 milligrams.

The deviation from the accepted method (that of administering gradually ascending doses up from a fraction of a milligram) was not owing to the absence of a proper spirit of caution, but came as the result of our experience with the first patients to receive tuberculin at Rutland, who from hearsay evidence were filled with distrust of the agent, and usually refused their consent to more than one injection. At one time it was in many cases impossible to obtain consent to even an initial dose, some patients preferring discharge to submission to a single injection. Since the successful use in later years of tuberculin as a therapeutic agent, consent to the test has been easily obtained and the graduated increase of the injections up from small amounts has been a much more general procedure. Patients with plenty of evidence of the disease may show reactions to an initial therapeutic dose of 1-100 or even 1-500 mg.[12]

The circumstances stated, which induced the administration of a large single dose of this diagnostic agent, also induced the physician to exhaust with the greatest care every other means of diagnosis, and encouraged especial thoroughness with both the physical and microscopical examinations. Patients having evident and definite physical signs at the apex of a lung would seldom receive a dose of tuberculin, and never a dose of large size.

In a few cases not mentioned in this tabulation, trust was placed in the establishment of the diagnosis by a smaller single dose. This was on account of the presence of more pronounced symptoms demanding greater caution in the exhibition of the agent. From the opening of the sanatorium in October, 1898, to June, 1907, while the writer was resident assistant to Drs. Bowditch or Otis, tuberculin was given diagnostically in initial maximum (10 mg.) doses, to 167 patients; reactions followed in 100, no reactions in 67. The per cent. of positives was 69.9; of negatives, 40.1.

Two of the number above, who failed to react, gave a little sputum, just before the injection with tuberculin, in which a few tubercle bacilli were found. There was no sputum obtained after this from these two people. One other patient, giving a history of rather large hemoptysis, without cardiac murmur or other assignable cause than tuberculosis, gave no evidence of a reaction to this dose of 10 mg.

In measuring the doses of tuberculin the greatest care was exercised to insure accuracy. The tuberculin was weighed and then diluted with sterile water to make a solution of such strength that each minim contained one milligram of tuberculin. The solutions were always freshly made.* A particular dropper was kept purposely for measuring the pure tuberculin. With this dropper it was repeatedly found that five drops weighed 180 mg. and one drop 36 mg. Consequently one drop of tuberculin thus measured, when diluted to 36 minims with sterile water, gave a solution of which 1 minim contained 1 mg. of tuberculin. Ten minims of this solution (measured with a special dropper) was put into an aseptic glass hypodermic syringe with enough more sterile water to make about twenty minims to be injected.

Estimating that nearly one drop of this might have remained in the needle uninjected, then the patient received perhaps one-half a milligram less than was prepared. As the Saranac tuberculin was always reported as a little stronger or more concentrated than Koch's standard, this loss was considered to have been overcome. The tuberculin used during the first five years at the sanatorium was furnished through the kindness of the Saranac laboratory. Dr. Baldwin described it as being, if anything, a little stronger than Koch's standard. Latterly some imported Koch's tuberculin has been used.

In none of the cases which received this maximum initial dose can it be said that anything more than perhaps a temporarily deleterious effect resulted. If special care, however, had not been exercised in the selection of the cases, without doubt considerable injury might have been inflicted.

The temperature reactions of the 167 patients who received the maximum dose initially were as follows:

32.13	per cent. had	99° to 100°
24.99	"	100° to 101°
21.42	"	101° to 102°
14.28	"	102° to 103°
7.14	"	103° or slightly above.

The reactions took place most frequently during the evening following that on which the injection was given, but in quite a number of instances the reaction did not occur until nearly 48 hours had elapsed.

The temperature and pulse were taken every two hours during the day and three or four times during the night on two or three days following the injection. It will be seen from this table that the majority had comparatively little fever (under 101°).

The daily routine was continued the same with all until the occurrence of a sufficiently marked reaction to necessitate rest in bed. As the height of the reactions occurred usually about bedtime, there were but few that actually became bed patients during the day as a result of the test. Only about 15 per cent. were kept in bed an entire 24 hours or more. This percentage of reaction seems low when contrasted with the reported results upon the soldiers in a Prussian regiment, where the reactions occurred in 60 per cent. of an entire company. The sanatorium cases were selected because suspiciously tuberculous. The Swiss-German recruits had been selected because supposedly sound. I have always felt confident that if these same Rutland patients could have had the identical dose of tuberculin while in their environment prior to admission to the sanatorium, the reactions would have been much more marked than was actually the case afterward while under sanatorium régime.

The open-air, rest treatment has a powerful effect upon any elevation of temperature produced through autoabsorption of tubercle virus. Why, then, should it not influence the temperature elevating power of tuberculin when deliberately injected?

Madison's[17] series of 400 consecutive patients admitted at the Danvers Insane Hospital reacted in 40 per cent. of the cases, and he quotes Beck's[18] series of 2,137 unselected cases with 1,154 reactions, or 54 per cent., and Zahn's[19] 6,320 autopsies in which he found tuberculosis present in 32.5 per cent. of all cases. In the cases at the sanatorium, tuberculin was not administered unless the presence of tuberculosis was strongly suspected. The patient was always admitted because of definite symptoms and generally because referred by some physician.

*Those who do not bear in mind the necessity for using freshly prepared solutions might be misled by the directions commonly given for preparing the dilutions, such as for example were given in an article on The Opsonic Index and the Tuberculin Test, by Rotch and Floyd:[16] "The solution for using this test is prepared as follows: One cubic centimeter of Koch's old tuberculin is added to 999 c.c. of boiled distilled water—one c.c. of this solution equals one milligram, the dose of this," etc. Without being cautioned against it, and having made up this solution of 1,000 c.c. for a few tests, an economist might save the bulk of the remaining solution for subsequent use, not realizing that for careful testing the dilution in a few days at most would be worthless. In a personal communication on this subject to the writer, Dr. E. R. Baldwin of Saranac stated in 1904: "I believe that it is often true that the preparation is not freshly diluted for each dose, nor always carefully prepared in making the dilutions. I have known at least one instance where negative results were uniformly obtained from an active tuberculin because the dilutions were not freshly made." The original concentrated tuberculin also tends to deteriorate in time, as shown by Madison,[17] who compared the contents of freshly opened bottles with that of those opened months before, and found less marked activity with the latter. Besides keeping it in "a dark, cool place" it is sometimes well to transfer it to a sterile tight glass-stoppered bottle, after opening the original package, because the glycerin which enters so largely into the composition of tuberculin tends to absorb moisture from the air, thereby slightly diluting the preparation.

I think that the data on the frequency of latent tuberculosis, which runs up into even much higher percentages than those given, has served merely to confuse and befog the minds of practising physicians when confronted with the necessity for making a diagnosis of the clinical type of early tuberculosis, and it furnishes them with an apparent excuse for not becoming especially active in the establishment of a diagnosis with suspected cases. There is, however, a vast difference between the latent or non-symptomatic and the active or symptomatic types of this disease.

In the opinion of all experienced observers 10 mg. is an unusually large dose and seldom necessary. Few certainly have had the temerity to give an initial maximum dose in so many cases. The practice is not advocated, but the statistics are offered in order to show the possibilities of the "clinical method" for the tuberculin test, and to estimate the degree of influence ascribable to a cumulative effect when tuberculin is given diagnostically in rapidly ascending or repeated medium size doses.

At the Massachusetts State Sanatorium since 1905 tuberculin in graduated increasing doses has been given to 96 patients. Reaction followed in 70 patients, or 72.9 per cent. The reactions with this method of dosage are increased 13 per cent. over those with single injections, and it will be seen that, owing doubtless to the cumulative property of tuberculin, a maximum dose given after a succession of smaller doses may sometimes cause a reaction when an initial maximum dose would fail. The interval between doses was about four days.

The subsequent history of the patients who were discharged on account of absence of reaction to tuberculin, although very incomplete, furnishes the fact that scarcely any patient reapplied for admission to the sanatorium, and this notwithstanding they were all cautioned to keep the possibility of tuberculosis in mind and return for examination if suspicious symptoms were noticed. The short period of education at the sanatorium which these people always had, doubtless must have been responsible for a considerable change for the better from their former mode of living, and this would exert a favorable influence upon their after history. With the patients, however, who, after reacting to tuberculin and remaining under treatment, were finally discharged with the disease arrested or apparently cured, there have been a few who have since relapsed, and two or three that, four to six years after their discharge, have died of tuberculosis. These data, so far as they go, indicate that the dose of tuberculin which was employed to differentiate the tubercular from the non-tubercular must have been essentially correct.

I do not believe we can ever know the exact minimum dose which will produce febrile reaction in health. Age, extremes in body-weight, the conditions of the nervous system, etc., doubtless would be factors affecting to a greater or less extent the size of the dose required.

Injections of sterile water have been used where it was thought that the neurotic element in a case would alone be responsible for some of the features of a reaction. In some institutions the initial dose of the tuberculin test is frequently merely water.

In using tuberculin diagnostically the lungs should be examined and the signs recorded before the test, and careful comparisons made about 24 hours and 48 hours after the tuberculin injection. The sputum, if any, should also be examined at this time, *i.e.* during the period of anticipated reaction. Occasionally the evidences of a reaction come only through these sources, the rise of temperature and symptoms of malaise being very slight indeed.

In order to give a still better idea of the character of the cases of suspected tuberculosis in which tuberculin was used at Rutland, I would say that of 2,749 patients admitted to the sanatorium in three and a half years, the first sputum examination revealed tubercle bacilli in 1,516 cases, later examinations in 477 cases. The sputum examinations were always negative in 640 cases, and there was no sputum at all in 126 cases.

Of these 757 non-bacillary cases, (*a*) 30 per cent. gave a history of hemoptysis and had definite physical signs of tuberculosis; (*b*) 28 per cent. had symptoms and physical signs so definite and evident that tuberculin was not used; (*c*) 24 per cent. were discharged, left of their own accord, or had such brief examinations that their cases were not classified or considered; (*d*) 20 per cent. were given tuberculin diagnostically, of these 60 per cent. reacted and remained, and 40 per cent. did not react and were discharged.

I think perhaps the most interesting fact which can be brought out in connection with these statistics is that, given the facilities for thorough search, it is possible to secure positive diagnosis without tuberculin in over 95 per cent. of all tuberculosis patients who are commonly seen by examiners for sanatoria, and this to a large extent excludes the hopeless cases. Even estimating that those patients who left the sanatorium almost immediately after entrance and in whom no proper examinations or tests could be made, would all have required tuberculin before 60 per cent. could be designated as positively tuberculous, then there would be but 200 (or 3.7 per cent.) out of approximately 5,331 applicants with tuberculosis, whose disease could not be positively diagnosed without tuberculin, and were diagnosed through sputum (89.9 per cent.) or by hemoptyses and other definite evidence (7.3 per cent.).

As only about one-third of the patients at Rutland have been admitted in the incipient stage, it is evident that this ability which we have shown in making a positive diagnosis of tuberculosis without tuberculin in over nine-tenths of all cases accepted, is not, after all, extraordinary. The average duration of symptoms in patients prior to admission has been every year, approximately, ten to twelve months.

It is well to note in the above that several hundred with incipient tuberculosis would have been left to the further unchecked ravage of the disease if reliance upon the first reported absence of tubercle bacilli had satisfied the physician's diagnostic curiosity.

Of 1,993 patients who had tubercle bacilli in their expectoration, and were resident at the sanatorium several months each, out of 14,000 microscopical examinations 708 patients only gave continual evidence of the presence of tuberculosis through their sputum.

It should be stated that the term "incipient" as defined by the National Association for the Study and Prevention of Tuberculosis, deals less with data which determine the duration of the disease than it does with points affecting the prognosis of the case. If the conditions are favorable and the lesion slight, tuberculosis need not necessarily be discovered early, in order to earn the appellation "incipient."*

*The Classification upon which applicants are admitted to most State Sanatoria is that adopted by the National Association for the Study and Prevention of Tuberculosis, viz.,

One might expect that physicians would use sanatoria oftener as places where suspected cases can receive the tuberculin test. Let us hope that conditions will improve and that, in the future, by assistance from anti-tuberculosis societies and health inspectors, physicians will be given an opportunity to see and pass careful judgment upon more cases in which the disease is slight or really beginning. Then tuberculin used both by the opthalmo method and by injection can perhaps be the most efficient single agent there is in lowering the death rate.

Class 1, Incipient (Favorable).—Slight initial lesion in the form of infiltration limited to the apex or small part of one lobe. No tuberculous complications. Slight or no constitutional symptoms (particularly including gastric or intestinal disturbance or rapid loss of weight). Slight or no elevation of temperature or acceleration of pulse at any time during the twenty-four hours, especially after rest. Expectoration usually small in amount or absent. Tubercle bacilli may be present or absent.

Class 2, Moderately Advanced.—No marked impairment of function, either local or constitutional. Localized consolidation moderate in extent, with little or no evidence of destruction of tissue; or, Disseminated fibroid deposits. No serious complications.

Class 3, Far Advanced.—Marked impairment of function, local and constitutional. Localized consolidation intense; or, Disseminated areas of softening; or, Serious complications.

It is the purpose and policy of sanatoria to admit at once applicants of the first class. Those of the second class are admitted if there are not enough of the first class applying to fill the beds, if in the judgment of the superintendent the treatment at the sanatorium will materially benefit them. those of the third class are not admitted nor are they advised that at any future time they will be admitted.

BENJAMIN RUSH AS A PHTHISIOTHERAPIST.

By HENRY FARNUM STOLL, M.D.,

HARTFORD, CONN.

"THE ancient Jews used to say that a man does not fulfill his duties in life who passes through it without building a house, planting a tree, and leaving a child behind him. A physician, in like manner, should consider his obligations to his profession and society as undischarged who has not attempted to lessen the number of incurable diseases." So runs the argument to Dr. Rush's essay on consumption.

Benjamin Rush was born in the year 1745 in Bristol, Pa., a town not far from Philadelphia. After graduating at Princeton College he studied medicine at the University of Edinburgh. Following which he spent some time in the London hospitals, and later, through the generosity of Benjamin Franklin, he was enabled to study in Paris. Thus excellently equipped he returned to Philadelphia, at the age of twenty-four, and soon became the leading spirit in the medical, social, and political affairs of the day.

Himself a sufferer from "a weak chest,"[1] which troubled him the greater part of his life, it is not strange that he took a great interest in the treatment of consumption. While a student at the University of Edinburgh he had been taught that tuberculosis was an hereditary disease and that the most salutary results followed the antiphlogistic treatment. This aimed, as the name signifies, at diminishing the inflammation *per se*. To this end only "nonstimulating" food was allowed, cathartics and emetics were freely employed, and the lancet was often unsheathed. It will be recalled that though tuberculosis was thought to be inherited in the north of Europe during the eighteenth century, in Italy, Morgagni and Valsalva were teaching that it was contagious and strict laws were enacted concerning it. This latter view Rush entertained during the early part of his practice, but later he had serious doubts concerning its validity. True he noted the occurrence of the disease in several members of a family, but he likewise saw epilepsy and madness visited upon families, and those maladies were surely not contagious. He observed that nearly all members of the family had poorly shaped chests, that all were alike subject to the same local condition—poor food, bad hygienic surroundings, etc.—and that they were debilitated as the result of administering to the sick one during the long illness and broken by the grief attending his death. Then, too, Rush averred that the fearful apprehensions of the surviving members of the family was sufficient to induce consumption. And if contagious, why was there often an interval of from two to ten years between the cases? In view of such logic it is not strange that the doctrine of the contagious nature of this dire malady was not generally adopted until the bacillus was discovered by Koch.

"I grant," he says, "that certain cutaneous humors and the matter of old sores, when repelled or suddenly healed, have in some cases fallen upon the lungs and produced consumption, but the consumption was preceded by general debility." In point of fact he considered it a "law of the system" that local disease was always preceded by general debility and in cases of consumption he frequently detected the symptoms of a general asthenia for several months before he heard "a single complaint

in the breast." Tubercles he considered as the result rather than the cause of tuberculosis. They were due, he thought, to mucus which was secreted in "prenatural quantity" as the result of the general debility of the bronchial vessels.

He attributed the greater prevalence of consumption among the women of the period to their light dresses which exposed the upper part of the arms, as that part of the body was thought to "sympathize" with the lungs in some mysterious fashion. The frequency of the disease from that supposed cause gave rise to the saying that "the nakedness of women is the clothing of the physician."

Inasmuch as Dr. Rush lived in the decade preceding Laennec, he did not auscultate his patients. Yet without a stethoscope, in ignorance of the tubercle bacillus, without the use of tuberculin, he diagnosed tuberculosis in the so-called "pretubercular" state. Attend to the symptoms he mentions as occurring during the first stage: "A rapid pulse especially towards evening, slight fever increased by the least exercise, burning and dryness in the palms of the hands, occasional flushing in one and sometimes both cheeks, a hoarseness, a slight pain in the breast, a deficiency of appetite, general indisposition to exercise or motion of every kind." [2] Is there a text book to-day which gives a clearer picture of the "prepulmonary" symptoms of tuberculosis?

In Dr. Rush's treatment of this malady we find much that is in accord with our ideas. Like Stewart of Erskine he likens the treatment of pulmonary ulcers to those in any other part of the body. "It is vain," he asserts, "to depend upon internal or external medicines. The whole system must be strengthened or we do nothing and it is to be effected by exercise and a generous diet." [3] The rank and file of the profession was distinctly opposed to this tonic treatment. Stewart in England was depreciatingly referred to as "a medico-clerical gentleman of consumptive notoriety," [4] and in France the tonic treatment as practised by Tronchin was described as being "as fantastic as murderous." [5]

Rush had little patience with the ill-advised symptomatic treatment. He says: "It is lamented that it is not in pulmonary consumption only that the effects of a disease have been mistaken for its cause. It is high time to harness the steeds which drag the car of medicine before, instead of behind it." [6] As a prophylactic measure he advised those with an hereditary predisposition to tuberculosis to choose a profession or occupation that required constant labor or exercise in the open air in all kinds of weather.

As the first step in treatment he insists on the removal of all causes, both remote and exciting, which are weakening the system. This not proving sufficient, cold baths, "steel" and "bark," were employed, and a moderately stimulating diet and gentle exercise was prescribed. When the pulse remained hard or was "rendered weak by a laborious transmission of the blood through the lungs," he bled to the amount of ℥viii. Blood letting as a cure for fever was thought highly of, as imparting strength to the body and removing the depression. His defense of blood letting in general is quite eloquent. "Go to those families in which I have practised for many years and inquire whether there is a living or dead instance of dropsy having followed in any one of them, the use of the lancet. Let the undertakers and grave diggers bear witnes against me, if I have ever in the course of my practice conveyed the body of a single dropsical patient into their hands by excessive blood letting." [7]

For hemoptysis he advised giving the patient a teaspoonful or tablespoonful of clean, fine salt—"poured down," he explains, "as soon after the hemorrhage as possible." In a number of cases he used two tablespoonfuls and repeated it for several days. His assertion that it "sometimes excites a sickness in the stomach and never fails to produce a burning sensation in the throat in its passage into the stomach, and considerable thirst afterward." [8] will be generally accepted as the truth without trial.

Dr. Rush mentions a number of persons who were cured when they changed their vocation to one which kept them in the open constantly. He cites the case of Dr. Latimer, of Wilmington, who greatly improved upon giving up his practice and entering the army. Spitting of blood returned, however, when he resumed his profession. "He had recourse to a low diet, but finding it ineffectual, he partook liberally of the usual diet of healthy men and he now enjoys a perfect exemption from it." [9]

He was a firm believer in exercise, but his watchword was "avoid fatigue," concerning which he said: "It is the hinge on which the recovery or death of a consumptive patient frequently turns." [10] Sometimes patients were put in a cradle out of doors and rocked to and fro, or a "chamber horse" was used. He cites one case where good results followed the use of a "chariot without horses," which was slowly moved back and forth by hand. Swinging, sailing, carriage riding, walking, horseback riding, and dancing were advised in certain cases. He deplored—as he would to-day were he alive—the loose directions given patients concerning exercise. He said: "That physician does not err more who advises a patient to take a physic without specifying its quality and doses than the physician who advises a patient in a consumption to use exercise without specifying its species and degrees." [11] He sums up the treatment as follows: "If it were possible to graduate the tone of the system by a scale I would add, that to cure consumption the system should be raised to the highest degree of this scale." [12]

Benjamin Rush, then, must be recognized as a pioneer in "modern phthisiotherapy," for apart from his belief in the virtue of blood letting his treatment differs but little from that employed to-day. And it must be regretfully acknowledged that in his recognition of the constitutional symptoms that characterize the disease during the so-called "pretubercular" or prepulmonary state, he showed an appreciation of the malady that is sadly lacking at the present time. All this is the more interesting when it is recalled that he practised medicine many years before Andrew Stewart, who appears to have been the first one in England to cut loose from "things antiphlogistic," graduated from the University of Edinburgh. And Stewart died at a ripe old age before Bodington read his paper which resulted in Brehmers' Sanatorium at Groerbersdorf.

THE MISUSE OF THE VOICE AND ITS CURE.

VOCAL MUSCLES AND RESONANCE.

By N. J POOCK VAN BAGGEN,

THE HAGUE, HOLLAND.

The exercise of the breathing and articulating muscles must always precede that of the vocal muscles. The pupil must have gained sufficient control over the breath and know how to direct the breath against the hard palate, and also the position of the tongue must be normal before the action of the vocal cords can be corrected.

The principal faults in the action of the vocal cords are made during the pronunciation or attack of the initial vowels. We distinguish three glottids or three different ways of attacking the initial vowel: the gradual or glide glottid or spiritus asper, the clear glottid or spiritus lenis, and the check glottid or shock of the glottis.

By the spiritus asper, the vocal cords are slowly contracted, they only approach each other gradually for phonation. In this case the voice is preceded by an emission of unvocalized breath, that means we hear an "h" and instead of ah ee oo, etc., we hear haa, hee, hoo, etc.

This way of attacking an initial vowel we especially notice when the vocal cords are weakened or when, as a result of catarrh, they close with great difficulty. In singing, the spiritus asper is heard but too often, when it may be a mere bad habit or the result of an insufficient control over the breath. Yet whatever is the cause of the spiritus asper it is a way of intonation which we must condemn and avoid because it fails precision and distinctness and because it is unpleasant for the hearer.

When applying the spiritus lenis, the glottis is in the position of phonation at the moment that the breath issues, and voice is produced instantaneously without the preceding of any unvocalized breath. The effect is a clear and distinct attack of the vowel. This is the normal intonation, which every singer and speaker should practise and use. Besides the pure emission of the voice it has the advantage, that it does not fatigue the voice needlessly, all superfluous movements of the vocal muscles being avoided, which is not the case, as we shall see, with the check glottid.

By the check glottid the vocal cords are pressed together and the thus retained breath causes a little explosion at the instant that the glottis is opened for phonation. We can best compare the movement of the vocal cords by the check glottid, with that of the lips when forming the letter "p." The explosion we hear by "p" is caused by the bursting open of the compressed lips which kept back the breath, while with the check glottid the compressed vocal cords retain the breath and cause the explosion when opened. The thus formed vowel might be called an articulated vowel. As it demands an extra effort from the vocal muscles and also because the compression of the vocal cords causes irritation, this way of attack must be avoided as much as possible and only be used when it is necessary, that is when a word beginning with an initial vowel must be accented.

Generally the shock of the glottis is not only too much applied but it is also misformed and thereby most of the harm is done. The shock which we hear by the patient in question is generally produced by a spasmodic contraction of the vocal cords, the result of which is an uneven or a too tight closing of those cords.

When the shock of the glottis is executed normally, with a sound use of the muscles, and well supported by the breath, it is a useful exercise to improve the closing of the vocal cords and to strengthen them.

Yet those exercises must be done with the greatest care and only in presence of the experienced teacher, who by the ear only can judge if the exercise is well done.

To break the habit of the too frequent use of the check glottid we operate as follows: when a word beginning with an initial vowel appears in the middle of a phrase, this word is united to the preceding one. This binding together of the words must be done very lightly and, for instance, must not be made as close as the "liaison" in the French language, where the final consonant of the first word becomes the initial consonant of the next. When the phrase commences with a word beginning with an initial vowel the spiritus lenis must be applied.

The first exercise for learning and practising the spiritus lenis is made as follows: Pronounce haa with a sudden expulsion of the breath by a swift contraction of the abdomen, making the h of haa as short as possible, while the breath is well directed against the upper alveolus, so that the tone is clear. Immediately after the thus pronounced haa try to form ah (without the preceding h, spiritus lenis) still in the same breath but now expelling the air slowly and carefully controlling it. The same exercise must be repeated with all the sounds.

To obtain good results with the above-named exercise, the example and help of the teacher is indispensable, especially because at first the pupil is not able to recognize a clear glottid from a check glottid or a gradual glottid.

As well as the attack, the release of the tone, especially in singing, needs exercising. The release of the tone is well done when the glottis opens at the same moment at which the emission of the breath ceases. Sometimes the glottis is opened before the emission of the breath ceases, in which case the tone is followed by a rustling of unvocalized breath; when the emission of the breath has ceased before the glottis opens, the tone breaks off suddenly. Hardly any direct exercise can be given to master the faults in the release of the tone; their correction must almost be done entirely by the hearing and imitation. A perfect control over the breath and a good knowledge and pure execution of the attack will help the pupil to free himself from this fault.

In his effort to make himself understood, the speaker but too often contracts the habit of raising his voice beyond its natural pitch, which means that the vocal ligaments are strained more than they can bear, and more than is necessary. As the fundamental tone in speech is different with each individual it is not possible to determine a certain limit of pitch for speakers. The teacher must find out the natural fundamental tone of speech of each pupil and then try to speak in this tone and make the pupil imitate it. When the teacher is not able to speak in the tone required for the pupil, exercises with the help of the piano can be made in the following way: Before each phrase, let the pupil hear the keynote of his speech and make him begin his phrase in that tone.

Yet as those latter exercises easily lead to monotony the first mentioned way of exercising is preferable.

There are but few singers who do not know the

difficulties which the registers of the voice offer to them and many are they who spoil their voice forever by the misuse of those registers! It is not the place here to give a full definition of the registers, which is the "*point de dispute*" in the art of singing. I can but give some principal hints on the treatment of the misuse of the registers. Generally the faults consist in the exaggeration of a lower register at the expense of the higher. Especially by dramatic singers this fault is frequent. There is no voice, however strong it may be, which can endure this overstraining of the registers and sooner or later the singer must experience the disastrous results of his or her fault. Hoarseness, fatigue, roughness, and impureness in singing and last, but not least, premature wearing out of the vocal organs are those results.

The exaggeration of the registers is generally united with a faulty breathing, which in the first place must be corrected. Only after good results have been obtained in regard to breath practice, will exercises for the correction of the use of the registers be made with success.

When the fault consists in the exaggeration of the low register, the singing in this register must be avoided for some time; when both the low and middle register have been used beyond their limit, exercises can at first be made only in the high register.

The pupil while exercising (in the first case in the middle and high register, in the second only in the high register) must limit himself to a few tones, singing always downwards and very softly. The tones will be weak, husky, and often impure in the beginning; by and by, however, they will improve. When those few tones are pure and clear, the pupil may extend the exercises downwards, always singing pianissimo and avoiding the lower registers. The high and middle registers or only the high register must be extended downwards as far as possible. Only after all the tones, sung as indicated, are clear and pure and have gained sufficiently in strength, may the low or the low and middle register be used again, but even then not more than is strictly necessary, while its diapason must be restricted to two or three tones below its natural limit.

The stretching downwards of a higher register at the expense of a lower register is also an excellent help to smooth the break in the voice at the passage from one register to the other. This stretching downwards of the higher registers always can be done without any danger to the voice. The "timbre" of the voice will even gain considerably in brilliancy and fullness by exercising in this way.

Closely united to the stretching and relaxing of the vocal ligaments is the moving up and down of the larynx. Many believe that the larynx must be kept as motionless as possible and in a low position. The large number of voices which have been spoilt by this unnatural fixed position of the voice-box are a manifest proof of the evil of this way of operating against which every singer and speaker must be warned.

The larynx must be completely free in its movement, its positions varying according to each tone and to the pronunciation of each vowel. We can easily follow the movement of the larynx by laying the finger on the prominence in the throat formed by the junction of the two wings of the thyroid cartilage commonly called "Adam's apple." When pronouncing successively "oo, ow, oh, ah, eh, ay, ee," we will notice that the voice-box rises and inclines slightly backwards and while by "oo" its position is lowest, it is highest by "ee."

Also when singing upwards we shall feel the larynx going up, while the inclination backwards can still be better observed than when pronouncing the vowels. When singing a high tone after a low one we can feel especially how considerably the position of the larynx changes, and it is clear that every obstruction in its movement hinders a normal voice production.

When examining the patient the teacher must observe the action of the larynx and feel if there are no spasmodic movements and if the flexibility is satisfactory. The action of the larynx can be exercised and improved by singing seconds, thirds, etc. The keynote always may be sung on *oo* the second, third, etc., on *ee*.

The resounding of the tone in the resonance cavities is of great importance to the speaker and singer. It is in the resonance cavities that the tone formed by the vocal cords acquires its accessory tones on which depend the characteristic sound of each vocal, the fullness and the brilliancy of the voice, and its "timbre."

It is in the first place for the pureness of the vocals that the resonance cavities and the accessory tones formed in them require our attention.

A vocal is no other than a tone formed by the vocal cords of which the vibration provokes the co-vibration, in the resonance cavities, of a certain amount of accessory tones of a determined quality. The quantity and quality of the accessory tones depend on the shape of the resonance cavities. By modifying the shape of the resonance cavities, tones of different qualities and in different quantities are put in co-vibration by the vibration of the keynote, or, what is the same, another vocal is formed. (For the modifications of the shape of the resonance cavities for the formation of the vocals see the article on "Articulation.") Ah has accessary tones different from ee or oo; ow from eh; ai from oh, etc.

In a series of vocals those next to each other, of which the formation differs but slightly, have accessory tones in common. In the series ah, eh, ai, ee, for instance, the "ah" has some tones in common with the "eh," like the "eh" with the "ai," and the "ai" with the "ee."

When the vocals are not pure this is due to the co-vibration of false accessory tones. This fault can be corrected by modifying the shape of the resonance cavities. However, this can only be done by changing the form and position of the soft and flexible walls of those cavities. The organic construction of the hard walls is unalterable and where this is the cause of the impureness of the vocal the fault is not remediable unless by removing a part of those walls—a dangerous remedy, because of the result being doubtful. As well as each vocal, each pitch has its own accessory tones. Yet, while the characteristic sound of the vocal is principally formed in the cavity of the mouth, the different pitches find their accessory tones in the various resonance cavities. For the lower tones the accessory tones lie in the chest and in the cavity of the mouth, the lower middle tones find theirs in the mouth and nasal cavities, the upper middle tones receive the co-vibration of tones in the nose and frontal cavities, while for the high tones the accessory tones are to be found in the sphenoid, frontal, and nasal cavities.

Like the vocals each pitch also requires a different shape of the resonance cavities. An exact knowledge of the place of the accessory tones and

of the form of the resonance cavities at each pitch is a first requisite for every singer. The misuse of the accessory tones is frequently the cause of a husky and impure voice. But too often we observe singers singing a high tone while the resonance cavities have the shape and the position of a low tone or *vice versa*. The correction of this fault is a part of the task of the teacher and of the pupil, which demands infinite patience and perseverance and which depends almost entirely on hearing and on imitation. Control over the breath and the exact knowledge how to direct the breath is in the first place necessary. The flexibility of the elastic walls of the cavities must be improved by exercise when needed; the soft palate especially requires our attention as to this. The singing or humming on "m," "n," and "ng" is a great help to make the pupil conscious of the place of the accessory tones in the upper resonance cavities.

When the organic construction of the hard walls of the resonance cavities is the cause of the huskiness or the impureness of the voice, exercises will hardly have any result at all.

When the lack of resonance is caused by the swelling of the mucous membrane which covers the cavities, the co-vibration of the mucosa must be restored. Humming on *m*, *n*, and *ng* is mostly effective in this case, which humming must be done as follows: begin with a middle tone and let the voice descend, gliding over the tones, then begin with a higher tone and do the same and continue till the limit of the voice is reached.

In this as well as in the preceding articles I have mentioned only the faults which are most frequent and the principal indications for their correction. My intention was only to give an *aperçu* of the treatment, which intention I hope to have fulfilled.

Plaats 10a.

THE FAVORABLE INFLUENCE OF SMALL DOSES OF ARSENIC AND BICHLORIDE OF MERCURY IN THREE CASES OF GRAVES' DISEASE.

By LEONARD WEBER, M D

NEW YORK

Among the twenty cases of Graves' disease of which I have records there is but one male, all the others are women between twenty and forty years old, none of whom were quite normal as to functional activity of the central nervous system. Only one acute case concerning a single woman of twenty-five terminated fatally by excessive hyperthyroidism and final cardiac failure.

Surgical procedures, such as Kocher's recent statistics have shown to be of great value in the severer forms of exophthalmic goiter, have not been done in any of my cases.

From Graves' and Basedow's time to near the end of the last century the disease was considered to be a vasomotor neurosis; rest, baths, change of scene, good nursing, the galvanic current to cervical sympathetic, and the administration of phosphate of sodium, 1 to 2 drams three times a day, according to Professor Kocher's own recommendation, were our main reliance. About 1805 Moebius came forward and said that Graves' disease was hyperthyroidism, that the perverted and excessive function of the gland was the cause of the entire symptom-complex.

His definition has been accepted, I believe, by the great majority of clinicians and practitioners, so that it is our task now to bring back the thyroid to normal function by medical means, or, if unsuccessful in such attempts, to have the gland removed in severe cases.

A sister of the young woman mentioned above who died of acute Graves' in about a year, came under my care in 1901. She was then thirty-one years old, married, 1-para, and presented both the cardinal symptoms of Graves' and various other signs of acute intoxication, such as marked tremor, sweats, frequent diarrhea, and later on enlargement of the liver and spleen. The usual plan of treatment being without avail and thyroidectomy having been refused, it occurred to me to try arsenic and corrosive sublimate for their antitoxic effects. The patient was ordered arsenic gr. 1/60 and sublimate, gr. 1/60 in tablet form, to be taken t.i.d.; and about one month after the introduction of these remedies she showed signs of improvement in all the symptoms. She continued to take them with but little interruption for nearly three years, recovered entirely, and has not been in need of any treatment the last two years.

In two other cases which have come under my care since 1903 I have had equally good results from the same remedies; however, they were not severe. I shall be gratified if this short communication will induce other practitioners to try the treatment in suitable cases.

25 West Forty-sixth Street.

The Smell of Paint.—The smell of paint occasions distress to a good many people and the spring cleaning season, when it involves the painting as well as the cleaning of the house, is dreaded, not on account merely of its interfering with the ordinary comforts and conveniences of the home, but because also in not a few cases a distinct disturbance of health is threatened. Persons who are sensitive to the vapors of paint, or, what is the same thing, to the turpentine and oils contained in the paint, are well advised to resign their homes until the drying influence of the air has dissipated the volatile oils. Turpentine, even in the form of vapor diluted with air, undoubtedly affects the health of some persons, the disturbance manifesting itself in the shape of giddiness, headache, deficient appetite, and anemia. There are headache, vomiting, swelling of the tonsils, albuminuria, and a marked rise in the temperature apparently due to an exposure to the emanations of wet paint for nearly a fortnight. That such a case should now and then arise is not surprising when regard is paid to the toxic effects which turpentine vapor is capable of setting up. Turpentine, in short, is a poison, and cats and rabbits are so susceptible to its action that if kept exposed to its vapor for some minutes they exhibit marked toxic symptoms ending in death if they are not removed from the sphere of action of the vapor. Personal idiosyncrasy, however, is clearly an important factor, for many persons and probably the majority do not seem to be affected by turpentine vapor to any serious degree. A very sensible precaution during the painting season for those to take who are compelled to endure the nuisance is to leave bowls of water in the freshly painted rooms. Some, at any rate, of the paint emanations are thus absorbed, as will be seen by the oily film on the surface of the water so exposed. An even more powerful absorbent is fresh milk which reduces the smell of paint in a room in a remarkable way. The poisonous effects of paint emanations do not appear to be connected in any way with the lead contained in the paint, the colic of painters being due to the actual contact of the person with the substance of the paint.—*The Lancet*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, February 8, 1908.

THE WIDESPREAD PREVALENCE OF PLAGUE.

THE recrudescence of plague in San Francisco, albeit on a small scale, cannot fail to bring to the minds of our readers the remarkable manner in which this disease has not only gained a foothold in different parts of the world, but has spread and appears to be spreading. The *Lancet*, in its issue of December 28, reviews as usual the chief happenings of the past year in medical circles, and no portion of this summary is more striking, and it may be said of more sinister import, than that which refers to plague. There is at the present time plague in India, in Afghanistan, Persia, China, Strait Settlements, Japan, Formosa, and the Philippines. It exists in Australia, on the Pacific slope of the United States, in South America, in various districts of Africa, in Turkey, in Asiatic and European Russia, and to a small extent in other parts of Europe. In Great Britain there were, during 1907, two cases of plague in Glasgow. Indeed, it may be stated that the malady is ubiquitous. In India the situation is appalling. The number of cases recorded in 1907 in that country is more than treble that in the previous year. The disease in Australia has shown itself sporadically in sections of that continent located at a considerable distance from each other. There are many places in which the disease has seemed to have disappeared, whereas it really was only dormant, or merely needed the presence of the conveyer of infection to initiate an epidemic or at any rate the dissemination of the malady on a more or less wide scale.

The experience of certain parts of Australia would appear to have been duplicated in San Francisco. There plague has not been evident, so far as was publicly known, for a considerable lapse of time. But in August of last year it again appeared in the chief port of California, introduced probably by vessels bearing infection from the pest-ridden Far East. Thence it traveled, or rather was conveyed, to other places in California, and found its way to Seattle.

The task would, however, be idle to point out the spread of plague throughout the world. Suffice it to say that it now is practically everywhere, and that the question as to its suppression is a most serious one with all civilized nations. Of course, it cannot be abolished. The labor of bringing this about would be too titanic for all the resources of science, money, and power. The state of affairs in India and China alone would render the consummation of such an object impossible. But it might and should be limited to the Far East.

Difficulties there would be in the path, but, taking into consideration the results which would accrue from gaining this end, no expenditure of money and energy would be too great.

At least now there is something to work on. It is known that rats are the chief, if not the sole, means of carrying the disease to far-scattered portions of the globe. The results of the observations by the several research societies in India during 1907 go to confirm the views already expressed by other investigators, that plague is conveyed from infected rats by fleas, and that when these fleas feed on man the disease is conveyed to him.

If, then, a successful war of extermination were carried on against rats, the prevalence of plague would be stayed. Again, it may not be feasible to slay rats wholesale in India, notwithstanding the fact that the assertion has been freely made that if all the energies of the Indian Government and its officials were bent on the destruction of rats, wherever found, plague would soon cease. Granted that rats cannot be destroyed in this way in India, it should be seen to in the most careful manner that the disease is not exported; that is to say, that rats are not carried on vessels that leave India or any of the Far Eastern ports. There are many obstacles to the successful conduct of this undertaking, but it cannot be truly said that these are insuperable. The plan would be expensive, and would entail much trouble for officials and captains of ships, and would be regarded in the fatalistic East as unnecessary. Laws, however, to this effect should be introduced and rigidly enforced, for civilized countries cannot be expected to bear the infliction of such a disease as plague, when they can be rendered free of its menace by the display of energy and by the spending of money. The whole matter is really an international affair, and all nations interested should quickly come to a definite understanding with regard to the measures to be taken to confine plague within what we may call its legitimate limits.

ROENTGEN-RAY TREATMENT OF PROSTATIC HYPERTROPHY.

IN the early stages of prostatic hypertrophy dietetic treatment may suffice to do away with the symptoms; in the later stages operative treatment or catheterization must be resorted to, the former often impossible on account of old age or enfeebled constitution, the latter always accompanied by the possibility of a cystitis or pyelitis setting in, even after thoroughly instructing the patient in the aseptic use of the catheter. Recently the fact that the action of the *x*-ray upon glandular tissues tends to cause their atrophy has suggested its application in cases of hypertrophy of the prostate. Thus Gautier of Paris, addressing the Congress of Sciences, held at Montarban in 1902, said that in his experience nothing compared with the *x*-ray treatment of hypertrophied prostate, he having obtained decided results in from four to eight sittings. Carabelli and Luraschi, however, in 1905, were the first to announce

definite results with the new treatment, having reported the cure of a patient with a greatly enlarged, hard prostate, who had 200 c.c. of residual urine.

In the January number of the *American Journal of the Medical Sciences* W. Hunter reviews the literature on the *x*-ray treatment of hypertrophied prostate and adds a case of his own. All the cases previously reported showed improvement, there having been a diminution in the size of the prostate as well as in the amount of residual urine and frequency of urination. His own patient was a man eighty years old who had a chronic cystitis for eight years, the urine containing large amounts of pus, but no cylinders. In February, 1907, prostatic symptoms set in, he voided urine as many as six times at night, had a burning sensation and pain during urination, and examination revealed a large prostate; the symptoms grew gradually worse until in April he was able to void only half an ounce of urine at a time and the residual urine amounted to 60 c.c. Operative treatment was manifestly out of the question so that *x*-ray treatment was resorted to. The patient received three exposures during May, the first two of twenty-five minutes, the third of fifteen minutes, after which, although all internal medication had been stopped, he enjoyed complete comfort until June 27, when the entire train of symptoms returned much aggravated. During July and August he received six exposures of from fifteen to forty minutes each, improvement having been marked after each treatment, until finally he urinated only once during the night, had no pain, passed a large, clear stream, and had only fifteen c.c. of residual urine; the prostate had diminished in size and the testes had atrophied.

Hunter prefers a high tube and uses a current of two ampères at 110 volts, placing his patient in the Sims position and directing the rays upon the perineum after protecting the surrounding soft parts with lead foil. In very old men he advises exposing the scrotum as well, as the good effect sometimes attending a castration can be added to that of the direct exposure. He has never seen any unpleasant results from the rays in spite of the long sittings, and believes that epididymitis and hemorrhagic cystitis which have been reported as caused by the treatment were due to faulty technique, the irradiation having taken place through the rectum.

It is entirely too soon to form any definite opinions as to the permanent cures to be obtained by this form of treatment, the reported cases having been too few. This much may be said, however, as there is apparently no danger connected with it and as it is easily carried out without any discomfort to the patient, it should be tried in all cases before an operation is resorted to and certainly in all inoperable cases when the patient would otherwise have to lead a catheter life. Only a few sittings are necessary to see whether it will do any good, an amelioration of the symptoms usually setting in after the first exposure. In all but the most pronounced cases of extremely indurated prostates the *x*-ray bids fair to surpass all other methods of treatment.

THE DISAPPOINTMENT OF MR. BOK.

A Mr. Bok, the proprietor of a female magazine, some years ago instituted a crusade against quack medicines, prosecuting it with a vigor and a fearlessness of the consequences which won for him much praise, and for his journal enthusiastic support from the lady members of the medical profession. He really did good work in a way and deserved all the material support which was given him, but, like many reformers, he didn't know when to stop or where to limit his efforts to better the world. The unstinted praise which he received from medical practitioners for his seemingly unselfish warfare against quackery, together with the injudicious flattery of a professional journal, inspired him apparently with the belief that he also had a mission to reform legitimate medical practice. Misled by a slightly unbalanced though highly esteemed contemporary, he adopted its views regarding the identity of quack medicines and proprietary pharmaceutical preparations and began a crusade against the latter. This was resented more or less, as meddling of outsiders in domestic disputes always is, and the chorus of professional approval suddenly ceased. The silence was painful to the strained tympanum of the reformer, and the mental reflex has been startling. It has driven him to a repudiation of all medicine—quack nostrums, synthetic remedies, and even the preparations of the Pharmacopœia, so dear to the heart of every earnest foe of proprietaries.

Mr. Bok has dropped us. In an address of which he recently delivered himself before the Philadelphia branch of the American Pharmaceutical Association he lamented the fact that his crusade had signally failed, and that physicians were now prescribing more proprietary remedies than ever before. In 1905, as he sorrowfully admitted, 41 per cent. of the prescriptions written in Philadelphia called for non-pharmacopœial remedies, and in 1906 this percentage had increased to 47. He could name, he said, sixteen leading practitioners of Philadelphia residing within six squares of the place where he was then holding forth, who continued to prescribe a certain "nostrum" which had been pronounced absolutely worthless by the *Journal of the American Medical Association*. This was too much! Lot had to move to get away from bad neighbors, and Bok is going to do the same. If the doctors won't prescribe the remedies of which he approves or will give those he has been told are bad, he will have none of them and it's osteopathy for him. In his own circle of friends, he said, fourteen families had, within a year, turned to "the drugless method of treatment" because they could not take "the chances with prescriptions," and Osler having gone there was no refuge but with Still. To help on the good work, we may note, and in witness of the editor's repudiation of drugs, good, bad, and indifferent, he has recently caused to be published in his journal a lucid exposition of the virtues of osteopathy, written by the founder of the school. In closing his valedictory address to the medical profession, the now thoroughly aroused orator intimated that though he had given us up he was not yet through with us, and

hinted darkly of some most damaging exposures which he had prepared, but was not yet quite ready to publish.

Mr. Bok's disappointment is due to the same error as the want of success of the would-be reformers within the profession. He confounded legitimate proprietary remedies with quack nostrums and included all, the good and the bad together, in one sweeping and intemperate denunciation. It was not his business, of course, to dictate to qualified practitioners of medicine regarding their treatment of disease, but had he been less obstreperous in his comments on certain abuses, which all admit need correction, his interference would have been received with the easy tolerance of a fairly good-natured profession.

Direct Transfusion of Blood in Illuminating Gas Poisoning.

The frequent occurrence of illuminating gas poisoning and the numerous deaths caused thereby make any good results in the line of treatment of practical importance. After a study of sixteen cases, all of which ended fatally, and none of which was treated by direct transfusion, and after a study of numerous cases reported in literature as cured by transfusion, Crile and Lenhart instituted some experiments to test the value of the various therapeutic measures suggested, especially blood transfusion, reporting their results in the October number of the *American Journal of the Medical Sciences*. Dogs were used, but no attempt was made to determine the exact proportion of gas in the mixture of gas and air, as it was thought that the best basis for comparison of therapeutic measures would not be the percentage of gas, or its time of action, but rather the exact condition of the animal as determined by ordinary clinical means, and especially by a manometric tracing of the blood pressure. The dogs were poisoned, and when the blood pressure reached a certain low point the various therapeutic measures were instituted and their results compared. In all cases respiration had stopped. In the sixteen cases recorded the heart had stopped in eight before any measures of resuscitation were taken. In six cases the heart had almost stopped with a blood pressure varying from 8 to 20. In two cases the blood pressure was 54 and 44 mm., respectively. One was saved by transfusion, the other died, notwithstanding the giving of saline infusion. Reduced to the low degree of blood pressure, 7 out of 10 dogs were rescued by transfusion of blood; of 6 others treated by the various other methods, all died. For the animal to recover it was necessary to begin transfusing immediately after the heart stopped beating, as the procedure is not efficacious after the heart stops finally, such, for example, as is adrenalin in chloroform poisoning. From the results of these experiments it seems fair to draw the conclusion that direct blood transfusion is of greater therapeutic value than oxygen inhalations, venesection, intravenous saline injections, and the other measures which have long been used in the treatment of illuminating gas poisoning.

The New Tuberculin Reactions.

Enough clinical reports have now been published in regard to the cutaneous and conjunctival tuberculin reactions of von Pirquet and of Wolf-Eisner and Calmette, respectively, to make it appear probable that the methods will prove to be of real utility. It is true that as in adults they indicate the existence even of lesions that are latent and encapsulated and may be regarded as of comparatively little importance, their results are of greater negative than positive value, but for children this objection has less force. A few instances of more or less serious ocular complications have been reported, misadventures which the friends of the conjunctival reaction ascribe to the use of a too concentrated test solution, and cases are not lacking in which the reaction was positive, but a subsequent autopsy revealed no tuberculous lesion, so that evidently an attitude of some reserve is still justified. That the matter has aroused great interest among clinicians is shown by the fact that a recent author was able to collect records of over 1,800 cases of the conjunctival reaction, concerning which the details have been published, with conclusions in favor of the method. Wolf-Eisner (*Berliner klinische Wochenschrift*, January 13, 1908) is firmly convinced of the reliability of the new procedures, and believes that they afford an insight into the powers of resistance of the body to the disease and that the nature of the reaction enables definite conclusions to be drawn in regard to the prognosis. For example, a very vigorous reaction in an early tuberculosis suggests a favorable outlook, while the opposite is true if the reaction is weak. In more advanced cases a strong reaction indicates the possibility of arrest or, at most, of very slow progress, while a weak response in late cases would indicate that the malady was making very rapid progress.

Early Mercury Treatment and Syphilitic Nervous Diseases.

The opinions of medical men as to whether energetic mercurial treatment in the early stages of syphilis can eventually prevent syphilitic diseases of the nervous system, are diametrically opposed. Most of the authorities simply express their views on this subject without giving any actual figures, large statistics being rare. Neisser found that forty-seven per cent. of 445 patients with tabes dorsalis had previously received antisyphilitic treatment in the early stages of the disease. The percentage was greater in a series of cases reported by Eulenburg and Dinkler. At the first annual meeting of German nerve specialists, held in Dresden, on September 15, 1907, P. Schuster reported ninety cases of tabes, forty-five of paresis, and 100 of cerebrospinal syphilis; of these 186, or 77 per cent. had previously undergone mercurial treatment, in fact 19 per cent. had as many as eight or nine series of inunctions. The time which elapsed between the appearance of the primary lesion and the nervous manifestations was no shorter in the patients who received no or only few inunctions than in those who received many. He made blood examinations in sixteen of his patients and found antibodies in the majority of them. The latter were present both in patients who had previously undergone mercurial treatment and in those who had not, and the clinical picture was the same whether the treatment had been given or not. Schuster by no means advises against mercurial treatment in the early stages of syphilis, for he does not deny the influence for good that such treatment exerts upon the course of the disease, but he asserts that his statistics show that such treatment does not prevent any future syphilitic affections of the nervous system, a state of affairs which he attributes to the fact that mercury does not eliminate the antibodies from the blood.

News of the Week.

The Illinois Sanatorium Bill, giving power to cities and villages in the State to establish and maintain public sanatoria for the treatment of tuberculosis, has passed the Legislature and become a law. The bill, which had the support and indorsement of the Illinois State Board of Health, and for the passage of which Dr. Egan, the secretary of the Board, is largely responsible, gives to each city and village in the State "the power to establish and maintain a public sanatorium for the use and benefit of the inhabitants of such city or village for the treatment and care of persons afflicted with tuberculosis, and to levy a tax not to exceed four mills on the dollar annually on all taxable property of such city or village, such tax to be levied and collected in like manner with the general taxes of said city, and to be known as the Tuberculosis Sanatorium Fund."

Tuberculosis Notification to be Made Compulsory.—Dr. Eugene H. Porter, State Commissioner of Health, has announced that the State Health Department is about to make an effort to secure the legislation to make notification and registration of cases of tuberculosis compulsory, and that a bill to this effect will soon be introduced in the Legislature.

Insanity Statistics.—According to the nineteenth annual report of the State Commission in Lunacy submitted to the Legislature on January 31, the whole number of committed insane on October 1, 1907, was 29,093. Of this number 13,927 were men and 15,166 women. The commission reports a slight improvement in the rate of recovery.

Diphtheria Cultures Not Mailable.—The Chicago Health Department calls the attention of physicians to the fact that they must not attempt to send diphtheria cultures through the mails. The postal laws absolutely prohibit the sending through the mails of any infectious material because of the danger of infecting the mails and thereby causing an epidemic of disease. The director of the Chicago Laboratory has been notified by the postal authorities that he must report all such violations to them, and physicians are warned that if diphtheria cultures are sent through the mails they will be immediately turned over to the postal authorities.

Army Medical Corps Bill Passed.—On January 28 the Senate passed the bill to increase the efficiency of the medical department of the army.

Antivivisection Bill Introduced.—The antivivisection bill, whose true purport has already been explained in these columns, has been introduced in the Legislature at Albany by Assemblyman Warren I. Lee.

Treatment of Bubo.—Dr. H. H. Morton writes that in his article on the treatment of bubo in the issue of January 25 the types made him recommend fermentations with acetate of ammonium, when what should have been printed was acetate of aluminum.

Korte's Birthday.—On the sixteenth of last month Privy Councillor Friedrich Körte, the dean of Berlin physicians, celebrated his ninetieth birthday, and numerous deputations from medical and other societies assembled in honor of the occasion. In spite of his advanced age Körte still enjoys remarkable physical and mental vigor.

International Conference on Sleeping Sickness.—The Second International Conference on Sleeping Sickness, which was to have been held in London on January 9, was postponed at the last minute owing to the fact that the French delegates had not been able to complete their preparations. It is expected that the conference will be held in a few months.

Against Cigarettes in New York.—At a meeting of the Board of Aldermen last week an ordinance was introduced with the object of restricting the sale of cigarettes or tobacco to minors under eighteen years of age. The penalty provided was $10 to $25 fine, ten days' imprisonment, or both. The matter was referred to the Committee on Laws and Legislation. An ordinance was also passed forbidding the smoking of cigarettes by women in public restaurants. The latter was promptly vetoed by the Mayor.

Famine in Lapland.—Despatches from Stockholm say that there is great distress through famine in the iron mining districts of northern Lapland. In the parish of Velhelmina the inhabitants have been reduced to using dogs and cats for food.

Russian Empress no Better.—The condition of the Czarina, who is suffering from a functional nervous disorder and general debility, is reported as no better, and it is stated that an ocular condition is present which will require operation.

Diphtheria in a Prison.—An epidemic of diphtheria is spreading among the 540 inmates of the reformatory at Rahway, N. J. Over fifty cases have already occurred and the drill room is being used to supplement the regular hospital. So far there have been no deaths.

Resisted Ambulance Surgeon.—When the ambulance surgeon of the Kingston Avenue Hospital sent to remove a four-year-old child from a tenement in East New York to the hospital attempted to take the patient away the family and neighbors offered forcible resistance, and four arrests were made before the ambulance was allowed to go.

Koch to Visit This Country.—In a recent interview Professor Robert Koch, who returned to Berlin a short time ago, after eighteen months' sojourn in Africa studying sleeping sickness, is reported as having announced his intention of taking a year's rest in travel, beginning with the United States. He is quoted as saying that he intended to leave for this country the end of March or early in April.

The Oldest Man in New England, according to the newspapers, was John Burrows, of West Stockbridge, Mass., who died on January 31, at the age of one hundred and six years. He had never used liquor and worked till he was over ninety.

New Training School for Nurses.—The managers of the Jewish Hospital, at Classon and St. Mark's avenues, Brooklyn, have decided to establish a nonsectarian training school for nurses in connection with the institution. The course will be of two years' duration, under the direction of Miss Simonson, superintendent of nurses. Pending the erection of a training school and home for nurses an apartment house near the hospital has been rented for their use.

Hebrew Charities.—Reports of sub-committees presented last week at a meeting of the Committee of 250, appointed recently by the Council of Jewish Communal Institutions to solicit funds for the United Hebrew Charities, showed that more than $20,000 has been obtained in new memberships and donations. The Board of Directors of the United Hebrew Charities has decided to continue its work through the winter months, but at least $40,000 more is needed to carry the society through its fiscal year ending next September.

Bequests to Hospitals.—By the will of the late John Lambert, of Philadelphia, the sum of $50,000 is to revert to the Pennsylvania Hospital after the death of certain beneficiaries, $25,000 to the Free Hospital for Poor Consumptives at White Haven, and $5,000 to the library of the College of Physicians of Philadelphia. By the will of the late Adeline S. Tryon, of Philadelphia, the sum of $1,000 is bequeathed to the Rush Hospital for Consumptives, St. Christopher's Hospital for Children, and the Kensington Hospital for Women.

Harvey Society Lecture.—The sixth lecture in the Harvey Society course will be given by Professor Joseph Jastrow, of the University of Wisconsin, at the New York Academy of Medicine on Saturday evening, February 8, at 8:30 P.M. Subject: "Subconsciousness."

International Congress in Electrology and Radiology.—The Fourth International Congress in Electrology and Radiology will be held at Amsterdam, September 1 to 5, 1908, in the buildings of the university. The program will comprise questions on electrophysiology and electropathology, electrodiagnostics and electrotherapeutics, diagnostics and therapeutics of Röntgen rays, the study of diverse radiations, and medical electrotechnics. In conjunction with the Congress there will be an Exhibition of apparatus and a collection of radiographs. The executive committee consists of the president, Prof. Dr. J. K. A. Wertheim Salomonson; the secretary, Dr. J. G. Gohl, and the treasurer, Dr. F. S. Meijers. The address of the committee is Vondelstraat 53, Amsterdam.

Medical Society of the Missouri Valley.—The spring meeting of this society will be held in Lincoln, Neb., March 19 and 20, under the presidency of Dr. W. F. Milroy, of Omaha, and the program is now open for contributions. The secretary is Dr. Charles W. Fassett, of St. Joseph, Mo.

Philadelphia Medico-Legal Society.—At a stated meeting held January 28 the following officers were elected for the ensuing year: *President,* Dr. William Ruoff; *First Vice-President,* Dr. J. Savidge; *Second Vice-President,* Dr. S. P. Gerhardt; *Secretary,* Dr. W. T. Hamilton; *Treasurer,* Dr. C. M. D. Peltz; *Censors,* Dr. F. J. Kelly, Dr. J. Wolfe and Dr. W. H. Robinson.

Chicago Ophthalmological Society.—This Society at its annual meeting, recently held, elected the following officers for the ensuing year: *President,* Dr. Thomas A. Woodruff; *Vice-President,* Dr. Charles P. Pinckard; *Secretary-Treasurer,* Dr. Mortimer Frank; *Councilor,* Dr. Thomas Faith, and *Alternate,* Dr. Willis O. Nance.

American Society of Sanitary and Moral Prophylaxis.—The next meeting of this society will be held at the Academy of Medicine on Thursday, February 13. Papers on the education of young people in the hygiene of sex will be read by President G. Stanley Hall of Clark University and Principal Frederick S. Curtis of the Curtis School for Boys.

The New York Medico-Legal Society and the American Congress for Tuberculosis will meet in joint annual session at Chicago, June 1, 2, and 3, 1908. The local committee of arrangements consists of Dr. Denslow Lewis and Dr. Thomas Bassett Keyes, of Chicago, and Dr. E. S. McKee, of Cincinnati. The latter was appointed to take the place of Dr. Nicholas Senn, recently deceased.

Northwestern District (N. D.) Medical Society.—At its meeting in Minot on January 4 this society elected officers as follows for the ensuing year: *President,* Dr. H. C. Windel, of Williston; *Vice-President,* Dr. O. W. Rowe, of Towner; *Secretary and Treasurer,* Dr. R. W. Pence, of Minot.

Nicollet and Lesueur Counties (Minn.) Medical Society.—Officers were elected as follows at the meeting of this organization held in Lesueur on January 24: *President,* Dr. G. F. Merritt, of St. Peter; *Secretary,* Dr. J. E. Le Clerc, of Lesueur; *Treasurer,* Dr. J. W. Daniels, of St. Peter.

Newport (R. I.) Medical Society.—At the meeting of this society held on January 24 the following officers were elected: *President,* Dr. S. T. Cottrell; *Vice-Presidents,* Dr. W. A. Sherman and Dr. M. H. Sullivan; *Treasurer,* Dr. P. A. Jacobi; *Secretary,* Dr. Mary E. Baldwin.

Yolo County (Cal.) Medical Society.—The following officers were elected at a meeting of this society held in Woodland on January 16: *President,* Dr. T. W. Gallion, of Davis; *Vice-President,* Dr. H. D. Lawhead, of Woodland; *Secretary and Treasurer,* Dr. F. L. Newton.

Chattahoochee Valley Medical and Surgical Association.—This association at its third semi-annual meeting, held in Columbus, Ga., on January 16, elected the following officers: *President,* Dr. J. H. McDuffie, of Columbus; *Vice-Presidents,* Dr. J. G. Palmer, of Opelica, Ala., and Dr. J. J. Wynn, of Clayton, Ala; *Secretary,* Dr. W. J. Love, of Opelica; *Treasurer,* Dr. A. J. Coley, of Alexander City, Ala.

Talladega County (Ala.) Medical Society.—At its annual meeting in Talladega on January 20 this society elected the following officers: *President,* Dr. E. T. Cason; *Vice-President,* Dr. E. H. Castleman; *Secretary,* Dr. C. W. Burtz; *Treasurer,* Dr. D. P. Dixson.

Memorial Services for Dr. Senn.—Memorial services in honor of the late Dr. Nicholas Senn were held in Music Hall, Fine Arts Building, Chicago, February 2, at 2:45 P.M., under the auspices of Rush Medical College, Northwestern University Medical School, College of Physicians and Surgeons, Chicago Medical Society, Chicago Surgical Society, and the Nicholas Senn Club. President Edmund James, of the University of Illinois, acted as chairman. Dr. Frank Billings spoke on "Nicholas Senn as a Teacher"; Dr. Arthur R. Edwards, on "Nicholas Senn as a Scientist"; Dr. William E. Quine, on "Nicholas Senn as a Man"; Dr. Henry B. Favill, on "Nicholas Senn as a Physician"; Dr. Albert J. Ochsner, on "Nicholas Senn as a Surgeon," and Dr. Daniel R. Brower, on "Nicholas Senn as a Traveler."

Obituary Notes.—Dr. EDWARD C. MANN, formerly of this city died on January 29 at his home in Stoughton, Mass. He was graduated from Long Island Hospital Medical College with the class of 1871 and was the author of several books on medical subjects.

Dr. CHARLES C. HOLCOMBE of Lee, Mass., died on January 31, at the age of seventy-eight years. He was a graduate of Yale Medical School and had practised in Lee for more than half a century. For a number of years he was president of the Lee National Bank.

Dr. WILLIAM J. KRAUSI of Brooklyn died on January 31, at the age of forty-nine years. He was graduated from the New York Eclectic Medical College in 1890.

Dr. JOHN J. GRIFFITHS of this city died on January 31, at the age of forty-nine years. He was graduated from the College of Physicians and Sur-

geons in 1883 and served as interne in Roosevelt Hospital.

Dr. Leavitt R. J. Varnum of Lowell, Mass., died on January 21, at the age of thirty years, after an illness of two days. He was born in Lowell and was graduated from Dartmouth and the Medico-Chirurgical College of Philadelphia.

Dr. Horatio C. Buck of Springfield, Ill., died on January 23, at the age of seventy-five years. During the Civil War he was surgeon of the Second Corps, and he was at one time president of the Tri-State Medical Society. He had been a member of the Pension Board almost continuously since 1877.

Dr. Stephen F. Pomeroy of Springfield, Mass., died on January 18, at the age of eighty years. He was born in Norwich, N. Y., and was graduated from Yale Medical School in 1855. He practised in Staffordville and Hebron before removing to Springfield in 1865.

Dr. H. J. D. Henning of Fargo, N. D., died on January 21, at the age of fifty-eight years. He was born in Wilkinsburg, Pa., and was graduated from the Jefferson Medical College of Philadelphia in 1878. He practised for a time in Beaver Falls, Pa., and Cedarville, Ohio, removing to Sheldon, N. D., in 1883. In 1890 he went to Fargo, where he had remained since that time.

Dr. M. C. Duncan of Madisonville, Tenn., died on January 18, at the age of sixty-one years, after an illness of three weeks. He was a brother of Dr. John Duncan of Atlanta and had practised in Monroe County for thirty-five years.

Dr. A. W. Riley of Omaha, Neb., died on January 31 of septicemia, contracted from a patient he was treating for erysipelas. Dr. Riley was graduated from the New York University Medical College in 1880 and had practised for ten years in this city before going West. He was a native of Plattsburg, N. Y.

Dr. Charles B. Fager of Harrisburg, Pa., died on January 24, at the age of sixty-five years. He was graduated from the medical department of the University of Pennsylvania in the class of 1864.

Dr. John P. Arnold died at Philadelphia on January 25, at the age of thirty-nine years. He was graduated from the medical department of the University of Pennsylvania in the class of 1893. He was subsequently resident physician and later medical superintendent of the Presbyterian Hospital.

Dr. A. B. Brumbaugh of Huntingdon, Pa., died of appendicitis at Philadelphia on January 27, at the age of sixty-three years. He was graduated from the medical department of the University of Pennsylvania in the class of 1866. He was surgeon to the Pennsylvania Railroad and to the Huntingdon and Broad Top Railroad, and he was one of the founders of Juniata College.

Dr. Joseph Thomas died at Quakertown, Pa., on January 28, at the age of seventy-eight years. He was graduated from the medical department of the University of Pennsylvania in the class of 1856. He was president of the Board of Trustees of the Norristown Hospital for the Insane.

An Inoffensive Light.—A convenient night-light for a sick room in a country house in which there is neither gas nor electricity may be improvised by hanging a lantern from a hook screwed into the bottom of an upper window sash on the outside. The light within the room may be regulated by raising or lowering the shade. This obviates the heat and odor from an ordinary lamp in the room.—*Nurses' Journal of Pacific Coast.*

Correspondence.

ANORECTAL FISTULA.

To the Editor of the Medical Record:

Sir:—In the issue for January 18 of your excellent journal I find an article of Dr. Charles B. Kelsey under the above title. Permit me to say a few words to Dr. Kelsey's paper.

It is a deep-rooted inclination of mankind to combat a new idea; Lombroso has called it "misoneismus." I have introduced, instead of this barbarous term, the name "misocainia," and Dr. Kelsey offers me the opportunity to add a new example of misocainia to those which I have collected from history and published in a paper, "Misocainia in Medicine," over three years ago.

I have demonstrated and published my observation that we can make the diagnosis if an anorectal fistula is a complete one or not by passing carbonic acid gas through the external orifice. When we inflate the rectum with the gas very soon a pleasant sensation of warmth will be felt, and this same sensation of warmth is experienced if the fistula is a complete one and the gas passes through the sinus into the rectum. In case the fistula is a complete one and neither tuberculous nor a syphilitic affection, the diagnosis will at once be the cure; that is, in a very few sittings the fistula will completely and permanently be healed. My first patients thus cured I have demonstrated before several medical societies and published these cases in several medical journals and in my book, "Carbonic Acid in Medicine." There are two sides to this cure of which not a word is mentioned in monographs on rectal diseases written by specialists of this branch of our art. It takes most thankful cases for operation from the surgeon and gives them to the general practitioner, who has no experience in operating upon rectal fistula. A special advantage of this method is that instead of causing pain, as probing does more or less, it is a rather pleasant procedure for the patient; where there has been pain the gas application will give relief.

A. Rose, M.D.

126 E. Thirty-fourth Street, New York.

CHLOROFORM ANESTHESIA.

To the Editor of the Medical Record:

Sir:—The several articles on chloroform which have recently appeared in the Medical Record have emphasized the commonly unappreciated fact that chloroform is no more fatal than ether if the more remote effects are taken into consideration. Another important factor, the skill and carefulness of the anesthetist, is too often ignored. An anesthetist who is more interested in the operation than in his patient is a dangerous man to give any anesthetic.

That the proper position, Trendelenburg, and artificial respiration *at once*, and not hypodermics, will save a patient, if anything will save him, who is not breathing and is pulseless from chloroform, must never be forgotten.

No apparatus can ever compare with a simple mask and a careful anesthetist who is giving either chloroform or ether by the drop method.

One point, and a very important one, has not been mentioned in the recent articles, and that is the proper cases in which to use chloroform. Chloroform is dangerous in myocarditis, fatty degeneration of the heart, dilatation from any cause, in uncompensated valvular lesions (not in well compensated valvular lesions), in cases of shock, great depression, or hemorrhage, in long operations, in joint manipulations where very deep narcosis is necessary, dental operations, in cases with tumors pressing on the trachea or larynx, in emphysema, in cases of cyanosis or dyspnea, in empyema, or where any effusion is to be tapped; and, lastly, chloroform has caused many deaths in children having the status lymphaticus, this including adenoids and enlarged tonsils, and chloroform should therefore never be used in operations for their removal. On the other hand, chloroform is particularly indicated in the two extremes of life, in nephritis, in stout patients, in individuals with atheromatous arteries, and in acute respiratory diseases.

As examples of the lack of judgment with which chloroform is often used, and the value or lack of value of statistics as to its safety, I quote nineteen deaths under its use from the report of the Anesthetists' Committee of the British Medical Association, published in 1900. One death was caused by the chloroform bottle falling over and saturating the patient's pillow—of course the death was due to chloroform; three patients had fatty heart; one had intestinal obstruction, four had empyema, one edema

of the lungs, one was suffering from urgent dyspnea, three were very exhausted, and two deaths were laid to the operation itself, leaving three cases of the nineteen not due to bad judgment. I could give many more illustrations, but it is not necessary.

All of the above means that each patient should be given the anesthetic best suited to his particular case, and that when one uses either chloroform or ether in every case, a certain number of patients are exposed to unnecessary danger.

THOMAS G. SLOAN, M.D.
SOUTH MANCHESTER, CONN.

THE TREATMENT OF NERVOUS INVALIDS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Dr. Robert T. Morris in the MEDICAL RECORD January 18, p. 109, in speaking of the sanatorium treatment of nervous disorders, neurasthenia, etc., asks: "Are there many sanatoriums in which the physicians make more than a shallow pretense at finding the real cause of the neurasthenia?" "Do they look for eyestrain or for loose kidneys or involuting appendices and the various well-known leaks below the water line?"

In making reply to Dr. Morris, it is not my intention to enter into any detailed discussion of the possible controversy which may exist regarding borderland conditions wherein surgeon and physician vie for honors, or even to discuss the treatment of neurasthenia and other psychoneuroses, which are now prominently in the limelight of both professional and lay opinion. I simply want to endorse what Dr. Morris has said, "that it is a profitless philosophy" to fire any system at us "for a flock shot" as a method of treatment, but I want to go further and say that this profitless philosophy applies also to the surgical shot delivered "below the belt" in the psychasthenic patient. Just here is where I would ask a question: Are there many surgeons who make more than a shallow pretense at finding out the real cause of the neurasthenia? Do they feel satisfied that in eyestrain, or loose kidneys, or involuting appendices, or the various leaks below the water line are the real causes of the psychoneurosis called neurasthenia? Are there many surgeons who proceed to study the real clinical psychology of their patient with a hope to find somewhere in the field of consciousness the mental perversion, the obsession which in itself is the disease and not the localized phenomena of which pain, anorexia, etc., are the prominent symptoms?

My experience teaches me a more profitless system, therapeutically (not financially) speaking, than that of surgical interference as a means for relief from the ills to which the psychasthenic is heir does not exist. Not only is it profitless, but it adds to the burdens of such an unfortunate one, whose diverse mental states are already wafted by the currents and counter currents of morbid self-consciousness, and not infrequently the surgical interference is the one necessary straw with which to break, perhaps forever, the patient's back. One who has seen much of the human wreckage which drifts into the sanatoriums from the operating rooms often has questioned his faith in the breadth of vision, depth of experience, and profundity of diagnostic acumen of some of the operators. One cannot help but feel that while modern surgery, with its masterly technique, whereby "beautiful" surgical results are attained, is a boon to humanity, yet it is also a fact that this brilliancy of results, technically speaking, too frequently is the license for needless deforming and unwarranted operations upon the defenseless suggestible psychasthenic. The misguided surgical enthusiast who sees no further than that part of the anatomy which he regards as offending, is responsible for much of the unnecessary surgery as practised upon nervous women. If he but knew more of physiological psychology, morbid thought processes in particular, he would find that many of his conclusions regarding surgical lesions were illogical and his generalizations unwarrantable. This unprepared surgical clinician should know how in nervous invalids the association of ideas which produces judgments just as frequently works in reverse order as well as along the natural parallel lines when associations of judgments and external excitants are intact. As a consequence, the association of ideas influences the sensations, and we have defined hallucinations of pain and other delusive ideas which lead the surgeon astray and compel the patient to believe herself the victim of a condition remedial only by surgical means.

Space will not permit me to go further into these processes of morbid disturbances, but they are familiar to all neurologists, and, I am pleased to say, to many of my skilled surgical friends. The trouble lies, I am sure, in the failure to recognize on the part of the gynecologist, the most frequent offender, as well as the surgeon, the fact that he is dealing with an individual, that the patient is an individual and the individual is the patient, and to know an individual means more than the mere study of an isolated part of her anatomy. It is therefore incumbent upon the trained clinician in gynecology to know his patients "above the belt," to know what should be the great ideal of every true scientist in medicine and surgery, the individual. To accomplish this, at least to the point of practical service, he must know human nature, which, after all, is but the reflected self, the reaction of the mental processes, the emotions, as shown in mental attributes and conduct, and with such a knowledge he could engraft a *profitable philosophy,* not only on his own useful life, but upon the lives of the introspective, impressionable, suggestible individuals who come to him as patients. Such a philosophy, perhaps, has not been dreamed of by the commercialized surgeon nor the surgeon working to complete a "new series of a hundred cases of," etc., but to the true clinician, guided by the true spirit of service, sacrifice of service if need be, such a philosophy will be profitable in creating confidence calculated to carry conviction and permanent relief to the obsessed nervous invalid.

What we need, and I am sure that Dr. Morris will agree with me in this statement, is more of genuine medical and surgical culture as the real incentive to honest, thorough, and scientific work. Then, in the wholesome atmosphere of such culture, we need not ask questions couched in the language of the satire of a Horace, but may we not hope for justice and the goodness as exemplified in a Marcus Aurelius?

FRANK P. NORBURY, M.D.
MAPLEWOOD SANATORIUM, JACKSONVILLE, ILL.

IODINE IN ERYSIPELAS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR—I read with great interest the article in the current number of your journal on the surgical uses of iodine. *In re* the use of iodine in erysipelas: In my profession we find an erysipelatous condition of the skin of cattle attacking *only the white or light colored skin:* thus we may see the white cutis hanging in rags, while the black is supple as a glove. As the old Higginbottom treatment of erysipelas with silver nitrate blackens the skin and as iodine temporarily discolors it, as (in my section) erysipelas is rare in the negro, is it not possible that the dark color shuts off certain rays necessary to the well being of the germ? A favorite, old-fashioned, "mother's remedy" is a cranberry poultice, and this, of course, stains the skin.

OUR LONDON LETTER.

(From Our Special Correspondent.)

SLEEPING SICKNESS CONFERENCE—PRACTICAL TEACHING OF MIDWIFERY—A MILD FORM OF DIPHTHERIA—THE SETON—COLLEGE OF SURGEONS AND WOMEN—ACTION FOR LIBEL AGAINST THE "LANCET"—SOCIETY FOR EXTERMINATING RATS.

LONDON, January 17, 1908.

THE second International Conference on Sleeping Sickness, which was to have met last November and was postponed to January 9 at the request of the German government, has again been postponed, this time, it is said, at the request of France, but will probably meet next month. There is some question of another commission being sent from here to Uganda to follow up the work of the Royal Society's Commission. It is in Uganda where the work is being carried on the largest scale, and the ravages of the scourge have been most terrible. There a system of segregation has been tried and, costly and difficult as it proves, much importance is attributed to it. There, too, the clearing of the jungle in the neighborhood of cantonments, ferries, and landing stages is being done as far as possible, but the immense distances are a bar to the clearance of the whole belt infected by the tsetse. Dr. Hodges of the Colonial Medical Service is directing the work in Uganda. A commission from the Liverpool Tropical School is also at work in Central Africa, and other investigations are being carried out by French, German, and Belgian medical expeditions. The postponement of the conference is perhaps not to be regretted, as no great discovery was to be reported. The disease is still extending its ravages

along the Nile and the Congo; some traces of it have appeared in Rhodesia. Where it originated is uncertain, but it was first observed on the west coast of Africa. In the nineteenth century it seems to have become firmly established from Senegambia to the southern limits of the Portuguese possessions. The transportation of negroes to the West Indies carried it across the Atlantic, and it obtained a footing in Brazil and some other parts of South America, but it has apparently not been able to maintain a hold in your hemisphere, though the fact of its once having appeared there is one for serious reflection.

The Dublin School of Midwifery has long maintained the chief position in these islands. Many earnest London students have gone over to obtain clinical instruction and more extensive experience than they could obtain here. It was, therefore, to be expected that the changes recently recommended by the General Medical Council should excite misgivings and lead to a discussion in the Irish Academy. Accordingly, the subject was brought before the Obstetrical Section by Sir Wm. Smyly, who said that the General Medical Council had been hampered by trying to reconcile the desirable with the possible. They could only make very moderate demands in England because the opportunities for teaching practical midwifery were very meager. But in Ireland, with her great lying-in hospitals, the position was different. A six months' attendance in one of these could be more likely to produce an efficient obstetrician than the recommendations of the General Medical Council, to adopt any of which would be a distinct retrogression. He admitted that the results of general practice in Ireland were unsatisfactory, but that could only be because the students had failed to profit by their advantages. To remedy this they must be compelled to attend demonstrations, and a desire to study practical obstetrics must be aroused in them by practical clinical examinations in the subject as recommended by the council. Every student should know that a knowledge of obstetrics and gynecology would go as far in passing as similar knowledge of the other departments. How to carry out this was the question.

Dr. Howe said men could be taken to a lying-in hospital for a clinical examination just as well as to a hospital for chest diseases. It was a grave defect that they had only to show they had taken out their attendances. Midwives in Dublin were better off, as they were compelled to attend daily.

Dr. Kidd suggested attendance on a number of cases in the house under the supervision of the medical officer, followed by the requirement to write full notes of the whole course of the puerperium in at least five of the cases. As to three or six months, a man living in the precincts of a hospital would learn more in a month than another attending full period on two days a week.

Dr. Purefoy said arrangements should be made for examiners to visit the hospitals once a month or so and examine certain students, thus obviating the necessity of taking many at one time. Students should also be encouraged to reside in a maternity hospital for at least a month.

Dr. Jellett said they would generally agree that the recommendations of the council were good except the reducing of attendance to three months. Students had a habit of going to maternity hospitals at times when they were free from lectures and examinations.

Dr. Rowlette objected to the excessive amount of surgery required by gynecological examiners. It was not the duty of the general practitioner to perform highly technical operations. Those who would be experts must make up after qualifying examinations were done with.

The President, Dr. E. H. Tweedy, said it was pleasant to see the unanimity with which the obstetrical section opposed curtailment of hospital work. Outside the section he regretted that many teachers thought a six months' course of obstetrics and gynecology unnecessary and there was danger that the royal colleges might cut it down to three months.

On the proposal of Sir Wm. Smyly, seconded by Dr. Jellett, a resolution was unanimously passed against reduction and in favor of a clinical examination.

Another resolution was also unanimously passed appointing a committee to urge upon the licensing bodies the inadvisability of curtailing the course.

Following this excursus into the domain of the Irish academy's doings, let me add a word or two on a paper in her medical section on an outbreak of sore throat. It was said by Sir John Moore, who called the disease "diphtheritic fever," though he might as well have used the adjective in *al*, for we do not use the noun in *itis*. In the cases he found the bacillus, but some of the typical symptoms were absent. The outbreaks (for there were five distinct occurrences) were in a girl's school, extended over a couple of months, and were followed by two sequels. The patients had coryza, tonsillitis, foul breath, coated tongue, desquamating, punctated rash on roof of mouth, swelled cervical glands, roseolar rash on skin (in twelve out of eighteen cases), and desquamation (three cases), most marked on the hands.

Dr. Kirkpatrick said ten or eleven recruits with similar symptoms sometimes came to his hospital in one day and soon recovered. In most cases there was a coccus, never a bacillus, nor had he seen a rash or enlarged glands or membrane.

Dr. Day said diphtheria was commoner in the city than was supposed. A membrane was not necessary to diagnose it. Bad teeth and constipation predisposed to it.

Professor White said the bacilli were exceedingly susceptible to desiccation, drying quicker than other organisms of similar virulence. This might account for some negative results of swabs.

Dr. Boxwell used the word attenuated to describe an organism he had often found in slight sore throat. It was rather smaller than the typical bacillus.

In reply to questions Sir John Moore said the mouth was attended to throughout in all cases. In nearly all the rash appeared before antitoxin was injected. The infecting organism was undoubtedly the bacillus diphtheria. He had found quinine a good disinfectant for the mouth.

Sporadic attempts to restore the seton to the favor it enjoyed in a previous generation are not without interest. Among the few practitioners who have lately advocated its use is Dr. Wilson Parry, who has modified the old seton needle by narrowing the shaft, so that when the head of the blade has passed through the fold of skin there is no further friction from the shaft or the tape.

Mr. Whitehead of Manchester reported in 1901 a case of migraine cured by seton after it had long defied other treatment.

Mr. Campbell and Dr. Parry have both recorded cases of Menière's disease relieved by the seton, and Dr. E. Pratt lately added one in which he had tried the seton successfully for symptoms suggesting cerebellar tumor in a child. In these days of asepticism the seton seems less formidable and prolonged counterirritation has been coming into favor, as in the use of blistering for rheumatic diseases.

Yesterday the council of the Royal College of Surgeons appointed a committee to prepare a circular to the members asking their views as to the admission of women.

The *Lancet* is being sued for libel in the King's Bench by a man who sells an asthma secret remedy which is shown to contain atropine and cocaine. The man professes not to know the composition of the liquid or to have any knowledge of drugs, but obtains the remedy from his brother in the United States. The alleged libel is defended as fair comment. As the trial is not concluded, no more may be added save to report that some doctors (and, of course, some fashionable lay persons) gave evidence in favor of the plaintiff. Among them was a hospital physician and Fellow of the College of Physicians, which august body is supposed to forbid dealings with secret or proprietary articles. What will the grave censors of this college say?

A new society was formed last week. Its object is the extermination of rats and other vermin. The meeting, at which the resolution was adopted, was attended by a number of doctors. Sir J. Crichton-Browne occupied the chair and in his speech described the ravages of rats and declared it was the duty of all to join in the crusade. With one dissentient—a lady who objected to any plan of killing rats which would entail suffering—the meeting agreed to forming the association and appointed Sir L. Brunton, president; Sir J. Crichton-Browne, Sir Patrick Manson, Surgeon-General Bradshaw, and Professor Simpson, vice-presidents. Several other doctors were appointed on the committee.

Gonorrheal Vaginitis.—In uncomplicated gonorrheal vaginitis J. W. Taylor advises a vaginal suppository of silver nitrate (gr. ¼) every night, and a douche of crude acetic acid (½ ounce to 1 pint of water) in the course of the day.—*The Hospital.*

OUR PARIS LETTER.

From Our Special Correspondent.

THE NOBLE PRIZE—LATENT TUBERCULOSIS—BACTERIOLOGY OF ARTICULAR RHEUMATISM—THE OPHTHALMO-REACTION WITH TUBERCULIN.

PARIS, December 20, 1907.

As is well known, every year the Swedish Government awards to one or more of the leading scientists of the world a prize of 190,500 francs. This year a Frenchman received the Nobel prize in medicine, the recipient being Prof. Laveran. The importance of his discoveries is widely recognized. In 1878 he discovered the hematozoa causing malaria and this advance opened an entire new world not only to general pathology but also to semeiology, hygiene, and preventive medicine. His researches have been collected in his "Traité du Paludisme." His later work on trypanosomes and trypanosomiasis shows what medicine may expect from an observer who like him devotes all his time and all his energy to laboratory investigations.

In the Société de l'Internat Bezançon presented an interesting paper on latent and attenuated pulmonary tuberculosis. Latent tuberculosis, he said, was extremely frequent and consisted in pleural adhesions, apical scars, or chronic pneumonia, that is, in cicatricial lesions. Some of these cases remained latent indefinitely and had no clinical history, others represented the first stage of evolution of the disease which did not appear until long after the onset of the infection, as the result of an overexertion, a traumatism, or an infectious disease. These latent forms of tuberculosis manifested themselves especially by changes in the breath sounds at the pulmonary apices, the general state of health remaining fairly good, and by occasional hemoptyses. Grancher deserved the credit of having pointed out the value of localized diminution of the respiratory murmur at the apices as an early sign of pulmonary tuberculosis. Laboratory methods, including the tuberculin test, the skin reaction, and serum diagnosis, although still of somewhat undecided value, could indicate to some extent whether the disease had already become active.

Thiroloix and Rosenthal presented a study of the bacteriology of acute articular rheumatism before the Société Medicale des Hôpitaux. By inoculating anaërobic media with blood from a rheumatic patient they regularly obtained a bacillus presenting all the characteristics of the organisms already described by Achalme and Thiroloix. The authors found that the bacillus was pleomorphic and that on becoming accustomed to aërobic existence it resembled a diplococcus. This fact explains the difference in results obtained by various observers. Triboulet and Silbert had also described the biological characteristics of the anaërobic bacillus reported by Achalme in 1891, and said that its constant presence in the blood in acute rheumatism justified considering it as the specific germ of the disease. While Thiroloix and Rosenthal had witnessed the transformation of the anaërobic bacillus into an aërobic diplococcus only in the test tube, Triboulet and Silbert had, on the other hand, detected both forms in the human body.

Sporotrichosis has lately been the subject of an investigation by the Société Medicale des Hôpitaux. Dominici and Rubens Duval observed a case of sporotrichosis of the index finger with secondary infection of the lymphatics. The patient was a woman who had inoculated her finger while peeling a potato. As a result of this invasion of the pathogenic mold a specific lymphangitis of the arm was caused. Beurmann, Gastou, and Brodier have also reported an interesting case of the same infection, which was particularly noteworthy because in addition to cutaneous nodules resembling those of tuberculosis there were also laryngeal lesions. The case was furthermore of importance from the etiological point of view, since for thirty-five years the patient had been a vender of salads in the public market and it therefore appears that sporotrichitic infection takes place through the intermediation of vegetables. Duval and Monier-Vinard studied the condition experimentally. Inoculation of the sporotrichitic pus into the guinea pig did not provoke any lesion, but mice and cats were susceptible to infection. In the pus obtained from human cases the parasite grew and formed a network of mycelial threads.

The society has also lately been devoting much attention to the value of Calmette's ophthalmo-reaction with tuberculin. Lenoble, Le Moal, Guichard, and Toché conclude from the study of 163 cases in which this method was used as follows: 1. That the procedure cannot be absolutely depended upon for diagnostic purposes, especially in doubtful cases. 2. That an individual who does not give the reaction is not necessarily free from tuberculosis. 3. That the reaction when positive does not necessarily imply that an active lesion exists and that it is possible that an individual having acquired a tuberculous lesion at some previous time may retain the property of giving the ophthalmo-reaction even after the lesion has become entirely cicatrized. Dufour also criticised the reliability of the ophthalmo-reaction. He had found that not all tuberculous persons, even excluding cachectic patients, react to the tuberculin, and he thought that in a large number of cases the interpretation of the results obtained by the method was an extremely difficult matter. Chaufard had recently seen a man suffering from chronic appendicitis who, from the clinical standpoint, seemed tuberculous. The ophthalmo-reaction was tried and was negative, but at the operation the patient was found to be suffering from tuberculosis of the appendix and cecum. Marcel Labbe obtained a positive reaction in the case of a patient who died later, but at the autopsy, although the most careful search was made, not the least trace of a tuberculous lesion could be found. Netter pointed out that some grave occular complications had resulted from this test. He also recalled the researches of Krause, who showed how easily the conjunctiva of typhoid patients reacted to tuberculin. Of twelve typhoid patients not suspected of tuberculosis eleven gave a positive reaction. Morax did not believe that there had ever been serious damage to the cornea caused by the application of the test. Comby concluded from a study of a large number of observations that in children the procedure was an infallible method of recognizing latent tuberculosis. He used a 1-200 solution of tuberculin and not a 1-100 solution, for with the latter he had experienced two violent reactions. Lesné regarded the ophthalmo-reaction as a perfect diagnostic measure. He had had only a single bad result in which a purulent conjunctivitis was caused from which the patient recovered completely. In adults he had twice in 150 cases observed instances of obstinate keratoconjunctivitis and he therefore now made use of a 1-500 solution, which was just as reliable in results and with which he had never had trouble. Mery Delille and Mlle. Jiry considered the ophthalmo-reaction as producing a grave reaction in infants. Massry, who had studied the method especially in adults, stated that it had not given him results in harmony with the clinical facts and the autopsy findings. He had three times obtained a positive reaction in a patient who on autopsy was shown to have died of generalized carcinosis, and he three times obtained a negative result in a case in which the autopsy verified the diagnosis of peritoneal and suprarenal tuberculosis. Achard and Feuille studied the effect of nervous lesions on the ophthalmo-reaction in patients suffering from peripheral facial palsy and hemiplegia, and had always found that the reaction was more pronounced on the paralyzed than on the healthy side. Most of the patients were entirely free from any demonstrable tuberculous lesion.

OUR LETTER FROM COPENHAGEN.

(From Our Special Correspondent.)

DIAGNOSIS OF APPENDICITIS—LEUKEMIA IN POULTRY—LIGHT BATHS IN HEART DISEASE.

COPENHAGEN, January 4, 1908.

PROFESSOR THORKILD ROVSING has published a method of examining the diseased cecum and vermiform appendix which promises to be of great help in cases where the diagnosis is difficult. In 1904 he had two cases of abdominal inflammation under his care, both of which, going by the usual signs, seemed to be cases of perityphlitis. The only difference was that the one patient experienced a very severe stabbing pain at McBurney's point when the descending colon was slightly compressed by a hand on the abdominal wall, while the other patient failed to feel the least pain in spite of rather vigorous massage of the colon descendens. On operation the first case turned out to be an ordinary appendicular peritonitis, while the last did not present any alteration of the appendix or gut, but in this case the colon was seen to be lifted up by a retroperitoneal swelling, a perineal phlegmon, which was opened by lumbar incision. Since then Prof. Rovsing has employed the following procedure as a routine examination in cases of disease in the right iliac

fossa. He applies his left hand, palm downwards, against the integuments of the left iliac fossa, and then exercises a pressure against it by means of his right hand, making the superposed hands glide upwards along the descending colon towards the left flexure. As a result of this procedure the gases contained in the large intestine are placed under a greater pressure than before, but the pressure is felt only in places in which the intestinal wall is in a state of inflammation, so that in cases of typhlitis or appendicitis a severe darting pain arises at McBurney's point on compressing the left iliac fossa. Judging from his experience in about one hundred patients examined during the last three years, Prof. Rovsing regards his method as a sure, sensitive, and valuable diagnostic help. Firstly, it will contribute to a correct diagnosis in the many cases in which the nature of a painful intumescence in the right iliac fossa cannot otherwise be ascertained, when, for instance, the choice stands between a renal affection, ureteric or hepatic lithiasis, salpingitis, and appendicitis. Only when the painful intumescence is caused by an inflammatory disease of the appendix or cecum Rovsing's method of compressing the healthy descending colon will elicit pain at McBurney's point. The second field for application of the method is formed by the acute cases in which a direct palpation of the right iliac fossa is dangerous, painful, or impossible on account of muscular contraction, and therefore best omitted. Here the compression of the descending colon quickly and without any danger to the patient gives rise to the typical pain at McBurney's point, if the case is one of inflammation of cecum or appendix.

At a recent meeting of the Copenhagen Biological Society Drs. V. Ellermann and O. Bang reported their investigations of spontaneous and experimental leukemia in poultry. With regard to leukemia it has up to now proved impossible to ascertain the true nature of the disease, some pathologists regarding it as an infection, while others consider it a sort of malignant new growth. As long as experimental transmission had not been carried out successfully, no progress could be made in this question. It fell to the lot of the two investigators first to observe true leukemia in a hen and afterwards to inoculate it into other poultry. The leukemia of poultry has not been described before; it is very similar to that of the human race. The increase of the leucocytes may become very considerable, the proportion of leucocytes to erythrocytes being as 1 to 2. The large mononuclear cells are particularly increased in number, and pathological forms are often seen (myelocytes). Besides the alteration of the blood, the liver and spleen become enlarged, the color of the bone marrow changes to a gray-red, and the capillaries of the bone marrow and the liver are filled with leucocytes. In the liver infiltrations of myelocytes may be observed. Intravenous injections of an emulsion of organs from a case of spontaneous leukemia produced in the course of three months leukemia in healthy poultry. The organs presented the same alterations as in the spontaneous disease. The different pathological processes apparently take place as follows: (1) Proliferation of the leucocytes in the capillaries of the bone marrow and the liver. (2) Anemia. (3) Leukemic alteration of the blood. (4) Infiltrations in the liver. The investigators failed to demonstrate the process of microbes. They are, however, disposed to regard the disease as an infection, and are now making further researches in order to decide whether this infection is due to the leukemic cells *per se* or to parasites.

I have on former occasions written you about the light bath treatment in heart diseases recommended by Dr. Hasselbach of the Finsen Light Institute. This treatment has been tried by Drs. V. Bie and H. T. Bing, who communicated their experience of it in the last meeting of the Society for Physical Therapeutics and Dietetics of Copenhagen. Instead of the expensive 150 amperes arc lamp, originally employed by Dr. Hasselbach, they had used "uviol lamps," *i. e.* incandescent quick silver lamps with uviol glass. These lamps were worked with a far weaker current and their light contained many of the effective ultraviolet rays, but only very few of the inconvenient and inactive heating rays. After an exposure of a quarter of an hour to half an hour with the lamps in a distance of 15 to 30 centimeters the skin showed a very pronounced erythema, which persisted the same length of time whether uviol lamps or the arc lamps had been employed. The erythema, having stood unaltered for about a week, gradually subsided, and after a fortnight the color of the skin was chiefly brown on account of pigmentation. But even several months afterward it was possible to demonstrate a slight remnant of dilatation of the skin vessels. Presumably this dilatation did not extend more than a few tenths of a millimeter into the skin, but even so it was no small additional quantity of blood that might be absorbed by the skin. They thought it impossible to state on the present standpoint of our physiological knowledge what this increase in the blood supply of the skin might mean for circulation. Next they reported their clinical experience. Their patients with heart disease had generally improved in so far as they slept better, or the pain and dyspnea became less marked. But unfortunately it was impossible to get reliable, objective criteria for judging the state of the patients. One patient with a mild form of Graves' disease had improved, but another became much worse after two treatments. They had seen the best results in cases of neurasthenia. The only indisputable effect of the treatment was the dilatation of the skin vessels, which might be of no small importance in diseases complicated with spasm of the peripheral vessels. But further researches were needed in order to arrive at the true indications for the chemical light bath as a therapeutic means. Dr. H. Jacobus, formerly of the Finsen Light Institute, mentioned the good effect he had observed on the pain in cases of angina pectoris. Professor Israel-Rosenthal was no great adviser of the new treatment. He had had under his care eight or nine of the patients treated in the Finsen Light Institute. Of these only one had improved considerably, but he regretted to state that the improvement did not prove lasting. For the other eight he had only observed a slight improvement, such as might very well be ascribed to the effect of suggestion, or no improvement at all. He was, therefore, unable to agree with the advocates of the treatment. Also other speakers attributed the observed effect wholly or partly to suggestion.

Progress of Medical Science.

Boston Medical and Surgical Journal, January 23, 1908.

Acetonuria and Laparotomy.—E. B. Young and J. T. Williams report two cases of acetonuria in fifty-two abdominal sections before operation and in twenty-seven in the same series following laparotomy. In minor operations, acetonuria followed in fourteen out of fifty-four cases. The test used was, acidification of the urine with glacial acetic acid, addition of sodium nitroprusside and overlaying with ammonium hydrate. Later they examined the urine of all patients on admission to hospital and acetonuria was found in twenty-six out of seventy cases. The authors refer to the literature of the subject as appearing in recent years. They conclude: (1) That acetonuria is a common accompaniment of a large number of pathological conditions. (2) That in these conditions it is the result of disturbances of metabolism. (3) That the occurrence of acetonuria seems to bear especial relation to disturbances of the gastroenteric tract. (4) That possibly many of the cases of reported acetonemia following operation were the results of other diseases, especially sepsis. (5) That the formation and excretion of acetone, and probably also of its supposed antecedents, diacetic acid, β-oxybutyric acid, etc., following operation, is the result of altered metabolism and, in the adult at least, not the cause of any constitutional disturbance.

Trypsin in the Treatment of Malignant Tumors.—W. P. Graves reviews the theories of Beard and other writers and then describes his personal experience with five cases of recurring mammary cancer and one of recurrent squamous-cell cancer of the uterine cervix. All had had done everything that surgery could do and the diagnosis had been verified by the microscope. All of the cases were observed for at least six months and most of them for fourteen months. Injections were given in the usual way—beginning with from 3 to 5 mg. of trypsin and increasing the dosage up to even 80 mg. In each case there was a gradual inevitable progress of the disease and four of the patients are already dead. In spite of these results the author has felt impelled to persist in its use. He notes that in recurrent breast carcinoma, it has been possible to keep well under control the nodules which make their appearance. A few injections of trypsin into one of these circumscribed nodules will cause it either to disappear or to shrink greatly, and that particular nodule will not grow again. This has been the most striking re-

sult of the treatment. The cervix case seemed to respond to the treatment more than the mammary cases. Treatment was kept np for six months in this case and during this time there was extremely small local progress of the disease in the vagina. There was practically no pain, and there was absolutely no odor from the cancerous cervix. The patient was able to be up a number of hours each day and was comfortable and happy. There was, however, a gradually increasing loss of weight and cachectic appearance, so that though the disease was being checked locally and symptomatically, it was constitutionally making progress. The patient finally died from inanition on account of a sudden occlusion of the pyloric end of the stomach. Operative measures were out of the question. As the patient became weaker during the last days, it was necessary to stop the trypsin treatment. Pain and the foul odor immediately appeared.

New York Medical Journal, January 25, 1908.

Unique Case of Infectious Orchitis.—The case is reported by J. G. Beardsley. A boy of eleven years returned home where his sister was sick with bilateral parotitis. He was ordered to use an antiseptic mouthwash and to keep as far away as possible from his sister. Eight days after his return he came down with a temperature of 102°, no pain or swelling in either the parotid or submaxillary glands, but a marked swelling of the left testicle, which was extremely tender to the touch, and the skin of the scrotum over which was decidedly reddened. The boy recovered completely in four days, and there was no difference in the size of the testicles. There had been no urethral discharge or no history of trauma, and as far as could be learned, no exposure to parotitis until his return home eight days before. Cases of parotitis have at times been reported, especially in epidemics, in which the swelling of the gland was very slight, and among them a few cases in which the parotiditis became visible only shortly after the patient was allowed to take fluid, but, as far as the author has been able to find in the literature (if we grant the possibility of the orchitis being caused by the infectious principle which causes parotiditis), this case is unique, although Osler mentions the fact that such a condition has been seen.

Postdelirious Alcoholic Stupor.—This topic receives a thorough consideration by C. K. Stillman. Its synonyms are "alcoholic cerebral edema" and "wet brain." A study is presented of ninety-eight patients, men and women, admitted to the alcoholic wards of Bellevue (New York) Hospital. Of this number twenty-two were attacked with "wet brain" and of this number eighteen died. Symptoms of the type of stupor referred to are almost invariably preceded by a greater or less degree of alcoholic delirium. The author notes that the type usually considered in speaking of alcoholic wet brain is a transudate pure and simple and not included under the category of the low grade meningitides. However, there is in alcoholic edema a tendency to low grade inflammatory changes about the blood-vessels and meninges that is far more marked than in wet brain of other types. Transudation takes place from the piaarachnoid and occasionally from the small blood-vessels penetrating the brain substance. About these latter a small watery zone may sometimes be made out. The changes in the brain substance and meninges are those so often described under chronic alcoholism. Symptomatology is fully considered. The diagnosis is not always easy. Pernicious malarial fever with meningeal involvement and tuberculous meningitis have been diagnosticated in cases which proved to be of the nature described by the author. Treatment is largely a problem of vitality and elimination, forced feeding and stimulation. Caffeine, camphor, and strychnine are reliable drugs. Alcohol cannot be cut off immediately. Tapping the cord produces results for a short time, say a day or so. The relief of pressure or the change in circulation incident to the removal of the fluid seems to cause a temporary accession of energy, so that a stuporous case may rouse up and assume for a short time the active movements and facies of an earlier stage of the disease. Indeed, there is not infrequently a resumption of active delirium until the fluid reaccumulates. No permanent results are noted. The fluid removed is usually in increased amount and under increased pressure. Otherwise, it differs in no respect from normal fluid either in appearance or in the distinctive count.

Cholelithiasis.—A study of twenty-five operative cases is made by C. H. Peck who gives his results in tabulated form. Six patients presented recurrent attacks of pain in the upper abdomen without fever, jaundice, tumor, or rigidity, and with but slight tenderness. Nine presented cholelithiasis with acute or chronic cholecystitis or empyema of the gall-bladder. Four had acute gangrene of the gall-bladder. One had calculi in the common duct and one primary carcinoma of the gall-bladder. Two died, one suddenly on the fourth day with symptoms suggesting cerebral embolism and one forty-eight hours after operation from general peritonitis. Of the operations performed twenty-two cholecystectomies resulted successfully, as did also one cholecystostomy, while two of the former were fatal. The author notes that cases of stone in the common duct require, in addition to the removal of the shrunken gall-bladder, incision into the common duct, removal of stones and thorough exploration of common and hepatic ducts to be sure that none are left behind. Hepatic drainage by means of a tube passed into the hepatic duct, around which the incision into the common duct is sutured, should be employed as a rule. Such a tube is removed in from three to seven days, the discharge of bile usually ceasing spontaneously at about the end of the third week.

Journal of the American Medical Association, January 25, 1908.

Cancer of the Breast.—The factors that unfavorably influence the prognosis of cancer of the breast are reviewed by W. D. Haggard, who specially calls attention to the importance of not neglecting any tumor, however small, in this situation, and the value of exploratory operations in such cases. He blames practitioners for the too common advice to wait. There is nothing more simple, he says, than the microscopic examination of a lump in the breast. The tumor, if small, can be easily removed through a slight incision, and if large, a portion can be removed and sent to a pathologist for examination, the wound being left open, with two or three provisional sutures and packed with Harrington's solution or alcohol to prevent any of the cancer cells from wandering into the blood-vessels and setting up metastases. Unfortunately, the surgeon seldom sees these patients early enough, and when operation is required it must be extensive to include all the possible lymphatic routes of infection. He sums up the contraindications to operation as follows: 1. Fixation to the chest wall. 2. Extensive axillary involvement when all the structures are fused. 3. Enlargement of the supraclavicular glands, which are secondary groups. 4. The "pig-skin" edematous lymphatics over the breast signifying that all the routes of lymph return are blocked. 5. Multiple shotlike nodes in the skin, commonly seen after osteopathic treatment, which bruises the vessels and spreads the cells over the chest with the formation of infected nodes. 6. Suppuration of the cancer itself (the only operative fatality in his series occurred in a case of this character). 7. Cachexia, the death mask of constitutional dyscrasia. The *x*-ray treatment is advisable, he states, after fixation, especially in advanced cases. While it does not kill cancer, except in very superficial forms, it will produce a higher type of local resistance, will contract lymphatics and will deposit fibrous tissue in and about the glands, thus delaying the progress of the disease. The principal points of the technique in operation for breast cancer are given.

Glycuronic Acid in Conditions of Diminished Oxidation.—C. W. L. Hacker reports the results of a search for glycuronates in the urine in order to test Mayer's claim that they appear as an early sign of incipient diabetes as a consequence of diminished ability of the organism to oxidize the carbohydrates. A second series of tests was so made of urines of patients after operations involving the use of chloroform or ether anesthesia which, as is well known, is followed by a diminished oxidation. In the first series of tests the glycosuric urines were examined quantitatively as follows: By means of Fehling's and Gerrard's titration methods, by Lohnstein's newest model of saccharometer, and by polarization before and after fermentation. In the second series of determinations qualitative examination was made before and after yeast fermentation, using Fehling's, Nylander's, phenylhydrazin, orcin, and polarization tests. Control urines before operation were also tested in the anesthesia cases. In the chloroform anesthesia, oxygen was also given, the average ratio being fifteen minims of chloroform and three or four liters of oxygen a minute. The merits and methods of the different tests are discussed at some length. In the first series of examinations 384 samples of supposedly normal urine and 14 of glycosuric urine were tested, and in neither were glycuronic acid or its salts found present in excess. In the second series 273 specimens were examined, 261 after ether, 7 after chloroform, and one after a mixed anesthesia with both. Control tests before operation showed no reducing compounds present. Eleven of the post-ether samples gave positive reductions with Fehling's test, and on further

investigation the reducing substance was found to be dextrose in amounts from 0.2 to 1.3 per cent. Hacker's conclusions are stated as follows: 1. Dextrose appeared in 4 per cent. of 261 samples of urine collected after operations in which ether was employed. 2. Neither glycuronic acid nor its conjugate salts are eliminated in the urine under conditions of diminished oxidation, such as occur during diabetes mellitus and ether or chloroform anesthesia, when the latter is combined with oxygen. 3. The pseudoreduction obtained with about five per cent. of normal urines is to be ascribed to faulty methods of performing the test. It is not due to an increase in amount of uric acid or creatinin.

Mutual Relations of Upper-Air Tract, Jaws, and Teeth.—W. S. Bryant considers the nose as the axis on which the facial development depends, and that any pathologic variation of this part produces trouble elsewhere. Most of the evils thus produced are traceable to mouth breathing due to nasal obstruction. Many evils, in his opinion, are traceable to this cause; besides oral infection and its consequences, we have imperfect development of the maxillary bones, dental irregularities and deficient development of the nose, sinuses, and all parts of the face. Any one of these factors may be primary, but the nose is usually first to blame. It is of extreme importance, therefore, to insure nasal breathing from the earliest infancy before habit is formed or structural changes are produced. If the obstruction is acute, as from catarrhal conditions, the prognosis is good; if chronic mandatory mouth breathing exists, the prognosis is good if surgical and orthodontal measures are resorted to soon enough, but after the twenty-fifth year it depends on the extent of the arrest in development. The sooner the defect is remedied the more simple and effective the treatment. "The importance of nasal breathing," Bryant says, "is manifold; it is a safeguard against infection, an aid to proper physical and mental activity, through a sufficient supply of oxygen, a requisite of moral strength, esthetic outlines, and a protection to the faculties of hearing, speech, and smell." The course of treatment to pursue if nasal breathing can be maintained, is to straighten the teeth first and operate on the nose later, if necessary. If it cannot be maintained, operate on the air passages sufficiently to allow nasal breathing before regulating the teeth. Then regulate the teeth, and, last of all, do what final work that is required on the nose.

The Diagnosis of Appendicitis.—R. T. Morris calls attention to the value of tenderness over the right sympathetic lumbar ganglion (one and a half inches from the navel on a line with McBurney's point) as a diagnostic sign in appendicitis in addition to the well-known McBurney's point. He gives the following general statement: 1. "In the early stages of an acute infective process of the appendix the right lumbar ganglia are tender and the left lumbar ganglia are not tender. (The left lumbar ganglia may be described for diagnostic purposes as lying an inch and a half to the left of the navel.) Under these circumstances the point here described is of secondary importance, while McBurney's point is of prime consequence. 2. (A) When an acute inflammatory process of the appendix has subsided, leaving a mucous inclusion or scar tissue, there may be no tenderness on pressure at McBurney's point, but there is tenderness at the point here described and no tenderness at the point of the left lumbar ganglia. (B) When the appendix is undergoing a normal involution process, with replacement of its lymphoid coats by connective tissue, digestive disturbances and various local neuralgia may be due to nerve filaments entrapped in the new connective tissue. There may be no tenderness at McBurney's point, but there is persistent tenderness at the point here described. There is no tenderness at the point of the left lumbar ganglion. 3. When the appendix is congested without the presence of infection, as in many cases of loose kidney, there may be little or no tenderness at McBurney's point, but there is persistent tenderness at the point here described. There is no tenderness at the point of the left lumbar ganglia." Under these conditions (A. B. C.) the point here described is of primary importance, while McBurney's point is of secondary or no significance. It will be found useful in differentiating between appendical and pelvic irritations. If it is alone tender, it means appendix trouble. If both right and left lumbar ganglia points are tender it signifies pelvic disorder. If neither of these points are tender, the abdominal irritation must be looked for somewhere higher up than the pelvis or the appendix.

Corneal Anesthesia in Cerebrospinal Meningitis.—E. Burvill-Holmes calls attention to a symptom of cerebrospinal meningitis that he has not seen noticed in the literature of the disease, viz., analgesia, or partial or complete anesthesia of the conjunctiva and cornea. He has found this sign in fully one-half of a large number of cases seen by him in the Municipal Hospital at Philadelphia, even in patients who were perfectly conscious in some instances. Occurring as frequently as it does, it would seem likely to prove a valuable sign in differentiating cerebrospinal meningitis from other diseases in which meningeal symptoms are likely to occur, such, for example, as typhoid and typhus fever and uremia.

The Lancet, January 11 and 18, 1908.

On Anomalous Reactions Obtained in Testing Urine for Sugar with Fehling's Solution.—H. Maclean gives a detailed account of elaborate chemical experiments which cannot be well abstracted and must be read in detail by those interested. He notes that the familiar Fehling test as applied to urine in general is complicated by many difficulties and ambiguities. He notes that different authorities seem to hold very divergent views with regard to the exact significance of certain results obtained with Fehling's test when the reaction is somewhat modified either with regard to the general appearance of the precipitate or the time taken to produce it. Thus on testing urine it is sometimes found that no result is evident after a good deal of heating with Fehling's solution, but that some time after standing an opalescent mixture is found to have taken the place of the blue solution, or perhaps there is a fairly definite yellowish-green precipitate. In other cases it is found that the mixture of urine and Fehling's solution gives on boiling for some time a dirty opalescent greenish milky liquid without any sign of a definite precipitate; at other times a more yellowish-green solution is in evidence; and all stages from a faint dirty greenish opalescence to a definite yellowish mixture exhibiting undoubted evidence of a precipitate may from time to time be seen in clinical work. The author declares that the substance interfering with the expected reaction is kreatinin. This has the power of holding in solution the reduced suboxide of copper. Were it not for this kreatinin every urine (since normal urine always contains a certain amount of sugar) would give a positive reaction. The author quotes freely from his previous papers on this subject and replies to the criticisms which Pavey has made on the correctness of his conclusions.

Further Observations on Salts of the Alkaline Earths Which Affect the Coagulability of the Blood.—J. B. Nias refers particularly to the lactate, borocitrate, and sulphate of magnesium, bromide of strontium and the lactophosphate and glycerophosphate of lime. It is the author's conviction that of all the alkaline earths none come up to the lactates, chlorides, and carbonates, if duly assimilated, and that we should rely on these for the treatment of hemophilia. For urticaria and conditions of general debility there is perhaps a larger selection.

On Blood Coagulability in the Puerperal State.—R. Hingston Fox describes the methods followed in his observations, his apparatus being a modification of that used by A. E. Wright (described in the *Lancet* of October 14, 1905). As Fox waits until the entire mass of blood withdrawn is coagulated, while Wright accounts the coagulation time to be completed before the first appearance of a shred of fibrin formation appears, the results of the two are not comparable. Fox gives, as a result of his own work, the coagulative time as varying from four to six minutes on the first day after delivery to seven to eight minutes on the seventh day. The patients were all recumbent in bed and the results are corrected for temperature. The author notes that an observation of the coagulation time of the blood after delivery might give useful warning of the risk of thrombosis or embolism if the coagulation time were low, or of post-partum hemorrhage if it were high. Appropriate treatment—for example, with citric acid on the one hand or with calcium lactate and salines on the other—would rectify the condition.

Bone Cavities Treated by Stopping with Paraffin.—The history of three cases is given by A. J. Walton, the cavities being respectively due to removal of sequestrum from the tibia, diseased bone from the humerus, and a cavity in the clavicle. All were filled with paraffin. The author states that to secure good results, attention should be paid to the following points: First, the wound should be carefully protected by gauze from contamination with the material in the abscess cavity or the irritant substances used to sterilize and to dry the cavity. Secondly, the operation should be completed in one stage so that good apposition of the edges of the periosteum and skin may be insured. This does not in any way seem to prevent the sterilization of the cavity, the only argument in favor of doing it in two stages. Thirdly, paraffin of a melting point of 120° F. should be used to fill the cavity. Many cases have now been recorded by Stephen Paget where its use

subcutaneously has been followed by success and one case where it was used to fill up a frontal sinus, the cavity in the bone being packed with it. It sets more firmly than Moorhof's mixture and can be sterilized more readily and has no local or general toxic characters, whilst the argument used against it that it is not absorbed does not from these cases seem to be correct.

Certain Papillary Signs in Chorea.—F. Langmead calls attention to the following: (1) Hippus.—The first is hippus. In many children who are more than slightly affected by the ordinary sthenic type of chorea the movements of the iris are extraordinarily wide and rapid. This is readily explained by the jerky movements of the eyeballs and the consequent quick and frequent variations in the amount of light which reaches the retinæ, and also the suddenly altering accommodation for the many objects which in turn are included in the visual field. This necessarily renders the detection of rhythmical oscillatory movements of the iris no easy matter, but during intervals of quiet these movements, which constitute hippus, are sometimes noticeable. (2) Peculiarities of movement of accommodation.—That the contraction of the pupils to accommodation may be extremely rapid and sudden has already been mentioned, but it will frequently be seen also that the reaction is asynchronous on the two sides, one pupil contracting, while the other remains temporarily dilated. This is especially marked when the pupils are unequal, the larger usually reacting more slowly. (3) Contraction.—Contraction of the pupils both to accommodation and to light is usually ill-sustained, and here again the affection may be unequal, so that when both are contracted one will sometimes be seen, as it were, to tire out and dilate whilst the other remains small. (4) Varying inequality of the pupils.—It may be noticed in some cases that one pupil remains persistently smaller than the other during the complete examination. This may continue for several weeks and only be replaced by the normal equality when the child has recovered or, on the other hand, when next seen the pupils may be equal or that which was formerly the larger may now be the smaller. (5) Eccentric pupils.—Eccentricity of the pupils may occasionally be present and may become better marked when the pupil is contracted and less obvious when dilated.

Arteritis Obliterans of the Lower Extremity with Intermittent Claudication.—The patient of F. P. Weber was a Russian Jew aged forty-two years, complaining of cramp-like pains in the inner part of the sole of the left foot or in the calf of the leg, coming on after he had walked three or four minutes. No pulsation could be felt in the left dorsalis pedic artery nor in the tibialis posticus behind the left malleolus. The areas on the left foot corresponding to the distribution of these vessels became red and congested-looking where the limb was allowed to hang over the side of the bed. After walking these same areas appeared blanched. This blanching could be lessened to some extent by amyl nitrate inhalations, but the internal administration of vasodilators did not appear to produce the same result. Rest, hot-air baths, Bier's method, and various applications were all of doubtful benefit. The case had lasted five years. The patient has been more or less threatened with gangrene in the shape of one or two small ulcerations but has thus far escaped. The author notes that the case is a typical one of obliterating arteritis which often leads to gangrene. He has found it rather frequent in poor Russian Jews who have been heavy smokers. The intermittent claudication has been regarded as analogous to the phenomena of angina pectoris and the malady has been styled angina cruris.

The Preparation of Catgut for Surgical Purposes.—Lord Lister notes the following as essentials for catgut in surgery. It should, after soaking in water or blood serum, be strong enough to bear any strain to which it may be subjected, and should hold perfectly when tied in a reef-knot. It must not be so rigid as it lies among the tissues as to have any chance of working its way out by mechanical irritation. Nor should it be too quickly absorbed, but should be consumed so slowly by the cells of the new tissue that grows at its expense, that in case of the ligature of an arterial trunk in its continuity, it may serve sufficiently long as a support for the substitute living thread in its embryonic condition. At the same time, it is essential that the catgut should be securely aseptic when applied. He finds these conditions best attained by preparing sutures and ligations in the following manner: The preparing liquid must be twenty times the weight of the catgut. So for 40 grains of catgut 800 grains of preparing liquid are required. It is made by mixing two liquids—namely, the chromium sulphate liquid and the sublimate liquid. The sublimate liquid is: Corrosive sublimate, 2 grains; distilled water, 320 grains. The sublimate may be dissolved by heat, but the solution must be used cold. The chromium sulphate liquid is prepared thus: Chromic acid, 4 grains, distilled water, 240 grains. Add to this as much sulphurous acid (P.B. solution) as gives a green color. If more is added the color becomes blue, which shows that rather too much sulphurous acid has been used. It is well to reserve a few drops of the chromic acid solution, to be added after the blue color has just appeared and restore it to green. Then enough distilled water is added to bring the green liquid up to 480 grains. Then add the sublimate liquid. The catgut is kept for twenty-four hours in the preparing liquid and is then dried on the stretch. (N.B.—It is essential that the CrO_3 and SO_2 solutions be mixed before the $HgCl_2$ solution is added.)

British Medical Journal, January 11, 1908.

Cancer, Its Etiology and Treatment by Trypsin.—Lowered vitality, whether due to faulty metabolism, alcoholism, overstimulation, diseases of the optic nerves, and general or local debilities is, in the opinion of J. Alcindor, the predisposing factor in malignant disease. Chronic irritation, of no matter what character, is the determining factor; the cells of the tissue irritated, unable to respond normally to the irritant, assume characteristics suitable for their environment, thus conforming to a natural law. Trypsin is of considerable value in cancer. Carcinoma of the cervix, rodent ulcer, and epithelioma are eminently suitable for the treatment. Gout, rheumatoid arthritis, and chronic rheumatism ought to be treated by injections of trypsin when other better known methods have failed. Regarding amylopsin, the author states that after injecting it singly and in combination with trypsin he has found it of no value in the treatment of cancer. He relates the histories of two personal cases, one of abdominal cancer and one of mammary cancer. Both cases eventually proved fatal, although the trypsin injections seemed to have exerted a marked influence on the original neoplastic deposits. Alcindor notes that trypsin does not seem to have any evil effect on healthy living tissues, but in the presence of an alkali it splits proteids into proteoses, peptones, and polypeptides; these are further split up into leucine, tyrosine, aspartic acid, hexone bases, and other amino compounds. It attacks all proteids alike, and exercises no selective action on cancer tissue. These facts would explain the reason why the two cases showed marked improvement up to a certain point; also why the first patient grew progressively weaker, while the second died rather unexpectedly from toxemia. The trypsin not only digested the growths but attacked the elaborated proteids, which were circulating in the blood for the nourishment of the organism, and converted them into toxic products; hence trypsin cannot be injected into the body for an indefinite period without producing deleterious effects, so giving rise to the very condition suitable for the growth of cancer. Alcindor is, however, convinced of the power of trypsin to digest cancer, but it must be applied directly to the disease and not in its neighborhood. Cancer of the internal organs cannot be successfully treated by this method, whereas rodent ulcer, epithelioma, and cancer of the cervix are eminently suitable for the treatment provided the cases are in the early stage.

The Pathology of Diabetes.—H. J. McNab states that whenever sugar is absorbed into the blood from whatever source all the body cells fix as much of it as they require in the form of glycogen, the liver perhaps having power to store whatever is in excess of immediate requirements. In order to make use of this glycogen it must be reconverted into sugar, and this, in the case of the liver, is done by means of a ferment. Now, this ferment may be the normal sugar-forming ferment of the pancreas, which, after performing its function in the intestine, is absorbed and made use of again in the tissues, perhaps undergoing some change till such times as it is wanted. When this ferment is not present, the glycogen in the cells cannot be made use of. But sugar may be an essential requirement of these cells, and, with the power of using the fixed glycogen gone, the small normal quantity floating in the blood may be of little use to supply this requirement. Hence a demand on all sides for sugar, resulting in increased appetite, and the conversion of proteid and anything that can be so transformed into sugar, so that the sugar percentage of the blood is raised above normal. But as soon as this occurs two things happen: (1) There is a demand for water, producing thirst, on account of the increased density of the blood, and (2) the kidneys begin to filter off sugar; so that, with abundance of glycogen and sugar, the tissues are starving for it, the cells striving to establish a higher sugar percentage in the blood, the kidneys always frustrating them. This theory would explain the good effect of pancreatic extracts in diabetes; the value of morphine may be simply that it diminishes metabolism.

Book Reviews.

Elements of Physics for Medical Students. By Frederic James M. Page, B.Sc. (Lond.), F.I.C., Associate of the Royal School of Mines; Lecturer on Physics and Chemistry to the London Hospital Medical College; Examiner in Physics and Chemistry to the Society of Apothecaries, London, etc. With a Colored Frontispiece and 230 Figures in the Text. Chicago: W. T. Keener & Co., 1907.

This is an excellent little book for anyone who has grown a little rusty in his physics and would like to refresh his memory without giving the time necessary to one of the large textbooks on the subject. The small size of the book, which can be easily carried in the coat pocket, together with the clearness of the type and the neatness of the illustrations makes it convenient to read on the cars or during any unoccupied minutes while waiting for a train, or at any other time. The subject is put in simple language, the explanations are clear, and the illustrations are all that could be desired to elucidate the text. The medical student who has taken a course of physics in school or college will find the book admirably adapted to freshen his knowledge. Part I deals with General Physics, Part II with Heat, Part III with Electricity, Part IV with Sound, and Part V with Light. Part VI is devoted to practical exercises on the subjects previously treated. An appendix contains a number of necessary tables. A good index completes the work.

Immunochemistry. The Application of the Principles of Physical Chemistry to the Study of the Biological Antibodies. By Svante Arrhenius. New York: The Macmillan Company, 1907.

Just as morphological pathology for the time being appears to have reached a point beyond which progress will probably be very slow while the greatest hope for the immediate future lies in the study of the chemical aspects of disease, so the problems of immunity, with all that this term implies, seem to await for their explanation a fuller understanding of the comparatively recent lore of physical chemistry. This science, occupying the middle ground between the chemistry and the physics of a generation ago, apparently is destined to bridge the gap between the two subjects and demonstrate that physical and chemical changes as we have been accustomed to regard them are in reality much more closely related than was formerly supposed. In the development of this difficult branch of learning Professor Arrhenius has played a prominent part, and when he turned his attention to the subject of toxin and antitoxin action it was to be expected that his investigations would be very fruitful. That they have been so is attested by the present volume, which is an amplification of six lectures on the immunity reactions delivered by the author at the University of California. It must be admitted, however, that the book is one more likely to prove of value to those already somewhat conversant with the subject matter than to the beginner, but special workers in this field will find it an exceedingly important guide and replete with evidences in favor of the chemical theory of vital processes.

The Pancreas. Its Surgery and Pathology. By A. W. Mayo Robson, D.Sc. (Leeds), F.R.C.S. (Eng.), London, and P. J. Cammidge, M.B. (Lond.), D.P.H. (Camb.), London. Illustrated. Philadelphia and London: W. B. Saunders Company, 1907.

One of the effects of the increased interest in the diseases of metabolism that has attended the gradual accumulation of the mass of chemical and experimental data that is now available has been to bring the pancreas—that organ of which it might truly be said that "it works in a mysterious way its wonders to perform"—most prominently into the foreground of both clinical and laboratory investigation. That the effort expended in this direction has been very fruitful is well illustrated by the difference in size between the senior author's former book, "Diseases of the Pancreas," published in 1903 in collaboration with Mr. Moynihan and having less than 300 pages, and the present volume, which is more than double this size. Of the nineteen chapters, the first six are devoted to a well illustrated discussion of the anatomy and histology of the organ. The chapter on the physiology is exceedingly interesting and lays due stress on Bayliss and Starling's "hormone" theory of the control of the secretion of the pancreatic juice. The two following chapters are on the pathology of the pancreas, while the next on the chemical pathology is one of the most original and important in the book. In this the authors discuss in detail the results of the analyses of the feces and urine in pancreatic disease, describing at length the technique of their "pancreatic" reaction in the urine for facilitating the diagnosis of pancreatitis. The succeeding chapter on diabetes is followed by one on general symptomatology and diagnosis, and the remainder of the work is given up to a discussion of the various surgical diseases of the gland. The book throughout is characterized by much originality, and its perusal opens up many suggestive avenues of thought. For example, the author's view regarding the intimate etiological relationships between gallstone disease and pancreatitis and between digestive disturbances, such as duodenal catarrh, and diabetes, have an intensely practical bearing. It is not too much to say that the work is one of the important books of the year, and that it can be most warmly commended to both surgeons and internists.

Primary Nursing Technique in First-Year Pupil Nurses. By Isabel McIsaac, Graduate of the Illinois Training School for Nurses; formerly Superintendent of the Illinois Training School for Nurses, etc., etc. New York: The Macmillan Company, 1907.

The object of this little book is to give the pupil nurse at the beginning of her training simple and definite instruction in technique. Throughout the book the teaching is addressed to the making of efficient nurses, and not the production of half educated physicians in the guise of overtrained nurses. The writer has given us a book that is practical and useful, and one which should be in the hands of all beginning their career as nurses.

Die Krankheiten des Verdauungskanals. von Dr. P. Cohnheim. 2te Auflage. Berlin: S. Karger, 1908.

The second edition of Cohnheim's treatise on Diseases of the Digestive Tract is a praiseworthy work. Everything has been presented from the practical point of view, and is given in a clear and concise style. There is no doubt that the present new edition will meet with as much success as its predecessor.

Ueber das Tasten Normaler Magenteile. Von Dr. Th. Hausmann. Berlin: S. Karger, 1907.

The present monograph deals with the subject of palpation of some parts of the stomach. In some instances Hausmann has been able to discover the pylorus, in others the lesser and greater curvature of the stomach (principally in cases with gastroptosis). Hausmann could palpate the pylorus in eighteen per cent. of the patients and the greater curvature in twenty-five per cent. He made use of deep palpation and thinks that this method is of diagnostic importance.

Traité de l'Hypnotisme Expérimental et Thérapeutique, ses Applications à la Médecine, à l'Education et à la Psychologie, par le Dr. Paul Joire, Professeur à l'Institut Psycho-physiologique de Paris. Président de la Société Universelle d'Études Psychiques. Avec 44 figures démonstratives. Paris: Vigot Frères, 1908.

More and more interest is being shown by the medical profession in psychotherapeutics. The works of Moll, Hirschlaff, Freud, Jung, and many others are more and more extensively read; and the present work of Professor Joire will also be found of value, although it is evidently written as much for the laity as for medical men. After discussing hypnotism as a means of psychological investigation, hypnotic suggestion, the hypnotic states, hypnotic methods, etc., the author describes its applicability in hysteria, obsessions, alcoholism, in the management of accouchements, in certain incurable maladies, etc. The action of hypnotism, he considers, is both physical and moral or mental. It diminishes or suppresses pain, facilitates general nutrition, overcomes insomnia, augments the forces, assists in restoring function, decreases depression and despondency, increases the courage, and both consoles and enlivens the patient when properly and successfully performed. Even if one does not wish to practise hypnotism, or hypnotic suggestion, the book will provide one with a knowledge of the subject and be convincing of its usefulness in some cases.

Nephritis. A Manual of the Disease Commonly Called Nephritis or Bright's Disease and of Allied Disorders of the Kidneys. By Seelye W. Little, M.D. New York: The Grafton Press, 1907.

In this book the author endeavors to present in a small manual the chief facts of interest to practitioners in connection with nephritis. The work does not offer anything really new, and contains much that is already well known and is taught in the standard works on the subject. There is a tendency to dwell upon some points with perhaps unnecessary persistence, as they are not moot points, but quite generally accepted. The style is a little jerky in places and verbose in others. For those who like discussion of a disease from a personal viewpoint, the book will be satisfactory.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

One Hundred and Second Annual Meeting, Held in Albany, January 27, 28, 29, and 30, 1908.

(*Concluded from page 204.*)

(Special Report to the MEDICAL RECORD.)

Wednesday, January 29—Third Day.

GENERAL MEETING.

THIS meeting was held in Centennial Hall, and consisted of a symposium on the upper digestive tract. This was arranged by Dr. Edgar A. Vander Veer.

Pancreatitis Resulting from Gallstone Disease.—Dr. WILLIAM J. MAYO of Rochester, Minn., read this paper. In 2,200 operations upon the gall-bladder and biliary passages the pancreas was coincidentally affected 141 times. As the total of all pancreatic diseases operated upon was but 168, 81 per cent. were due to or accompanied by gall-stones. In 268 operations upon the common and hepatic ducts the pancreas showed disease in 18.6 per cent., against 4 45/100 per cent. where the gall-bladder only was involved. In 124 cases the head of the pancreas showed evidence of inflammation, while in but 17 was the entire organ affected. Three cases were of acute pancreatitis, nine of subacute, and 129 chronic. The pancreas lay in a most protected situation, and was little liable to intrinsic disease. Its natural defenses had but a single defect and that was the mechanical association of the main pancreatic duct with the common duct of the liver. Inflammations of the pancreas were dependent upon infections or chemical irritation. In 62 per cent. of human subjects the terminal third of the common duct was imbedded in pancreatic tissue, while in 38 per cent. it lay behind. Therefore, 62 times out of a hundred any structural change in this portion of the head of the pancreas would interfere with the liver excretion through the common duct, giving rise to jaundice, while a stone in the terminal portion of the common duct, or infection caused by stone in any portion of the bile tract, exposed the pancreas to infection. Should a stone in the common duct compress the pancreatic duct of Wirsung, the safety of the pancreas might depend upon the possible presence of a patent duct of Santorini. Or if the stone lay in the papilla, the bile might force its way up into the duct of Wirsung, and set up chemical pancreatitis. The *triangle of pancreatic inflammation* was that part of the head of the pancreas which lay between the duodenum on the right and the ducts of Santorini above and Wirsung below. The most interesting feature of acute pancreatitis concerned fat necrosis, a disseminated necrosis of fat due to the escape of pancreatic ferments which involved to a greater or less extent the omentum, mesentery, retroperitoneal, and other adipose tissues. Fat necrosis was probably the result not of normal pancreatic secretion, but rather of pancreatic juice which had become activated by associated ferments either from the bile or from the duodenal mucous membrane. Of chronic interstitial pancreatitis there were two forms: The interlobular and the interascinar. The interlobular was fortunately the one most often associated with gallstone disease. In this type the pancreas was enlarged, nodular, and rough to the "feel," greatly resembling cancer. The interascinar often destroyed the islands of Langerhans, causing diabetes.

Duodenal and Gastric Ulcers.—Dr. ALBERT J. OCHSNER of Chicago read this paper. He said it was proper to consider these ulcers together, because the stomach and duodenum were so closely related anatomically, physiologically, and pathologically, and embryologically both were formed from the fore gut. The stomach had five functions which should be borne in mind. 1. It stored the food taken at one meal. 2. It secreted digestive ferments which acted in an acid medium. 3. It acted as a mixing machine. 4. It ground the food into the proper consistency. 5. It acted as an absorbing surface. The duodenum served simply as an extension from the stomach, in which small portions of food were subjected to mixing, but in an alkaline medium. As regards the etiology of gastric ulcer, traumatism from within was the chief exciting cause. The vast majority of cases occurred in the pyloric end of the stomach. Another etiological factor was the theory that certain antibodies were present or absent under certain conditions which prevented the gastric juice from digesting the mucous membrane of the stomach. This seemed to be borne out by animal experimentation. Duodenal ulcer was due often to an extension of a gastric ulcer, the so-called "saddle-shaped" ulcer of the pylorus; it was also due to the irritating effect of the gastric juice, a form of what might be called peptic ulcer. Duodenal ulcer might be caused by severe burns of the skin and by thrombosis of the vessels supplying the duodenum. The frequency, relatively, of duodenal ulcer was greater than formerly supposed. He referred to the remarkable studies of Cannon. The stomach and duodenum were the machines for getting food into proper condition for use later on. The digestive apparatus should not be interfered with surgically needlessly, because in ulcer of the stomach or duodenum the patient's digestive apparatus often could be restored to the normal without surgical interference. In the early stages, dietetic, medicinal, hygienic, and other measures should be employed. He emphasized the importance of giving dietetic and hygienic instructions to patients to prevent recurrences after the ulcer had healed. There were many cases, however, in which a permanent cure was not possible, and the sooner surgical relief was employed the better. The complications to be considered in cases of persistent gastric ulcer were perforation, hemorrhage, emaciation, adhesions to surrounding structures, and the implantation of carcinoma. At the beginning of an attack it was not possible to differentiate the class of cases requiring operation from those which would heal spontaneously. To protect the ulcer, much mucus was secreted. Hydrochloric acid was also secreted in large amounts. There was also hypertrophy of the muscles of the stomach. All this tended to increase the irritation of the ulcer. These changes were likely to do more harm than good, although the physiological intent was to protect the patient. The ulcer might encroach upon blood-vessels; it might perforate into adjoining organs; or carcinoma might be implanted. Most commonly there was an obstruction at the pyloric end, due to induration at the base of the ulcer. This obstruction might be overcome by hypertrophy of the muscle; if not relieved by this, this is followed by an exhaustion of the muscles and consequently gastric dilatation. He recalled such a case in which the lower end of the stomach rested in the pelvis. Because of the residual food in the stomach the patient absorbed products of decomposition instead of the products of digestion. This accounted for the cachexia, which was invariably present in these cases. This explained the favorable results which followed gastric lavage. With efficient drainage by gastroenterostomy the patients were made much better. He emphasized the fact that the technique must be learned at the operation table. There was no operation in the field of surgery in which there were so many failures if the operation was learned on the cadaver or from a description as this particular operation. Certain fundamental principles must be observed to reduce the mortality. (1) The amount of traumatism must be reduced; (2) the intraabdominal organs should be exposed as little as possible to the cold air; (3) the patient

must be placed in the sitting posture as soon as possible after the operation; (4) in case of closing perforations the sutures must be so placed as not to result later in obstruction from contraction; (5) in case neoplasms are to be enucleated, all the tissues closely connected by lymphatics must be removed; (6) in gastroenterostomy the lowest portion of the stomach must be chosen; (7) there must be no tension upon the sutures; (8) except in complete gastrectomy the coronary artery must be preserved; (9) in acute gastric dilatation the stomach tube must be at once introduced and gastric lavage employed; (10) the simplest possible technique must be employed preferably without use of mechanical apparatus; (11) these patients should be controlled for a long period of time after operation and instructed as to their diet and general hygiene.

Surgery of the Liver and Gall-Bladder.—Dr. JOHN C. MONRO of Boston read this paper. He said he would confine himself to the bringing up of the more vexatious problems, and first considered the question of syphilis of the liver as a surgical disease. Writers agreed that certain cases could not be diagnosticated without operation, and many of them even required to have a microscopical examination to confirm any diagnosis. Among their cases the non-operative cases, a marked syphilitic history was an important factor. The lesions were gummatous, and they might become cheesy or calcified. Pedunculated tumors formed because of the contractions which formed. In the hereditary form the condition was usually interstitial. Evidences of a grave infection might be found. Ascites was said to be present in all cases by some writers. Jaundice was not common or severe. The gummatous tumors were somewhat common in the region of the suspensory ligament. They were hard and irregular. The larger ones might be soft and tender. Symptoms of gumma of the liver might be entirely wanting. Or they might be such as to appear to threaten life. The pain was apt to be nocturnal. The loss of strength and weight might be so marked that malignancy would be thought of. In their experience constipation and not diarrhea was more often met with. Cancer might be excluded because it rarely was primary in the liver. The therapeutic test was valuable in differentiating, but it should not be wholly depended upon. Dr. Monro then gave a brief analysis of cases. Another question that might arise was, what was the proper treatment of the cases that died a few hours after operation from complete suppression of liver function. They had all the signs of septic infection. In cases of hemorrhage of severe type, calcium salts and similar agents might be used with advantage. He then considered cholecystectomy *versus* cholecystotomy. The patients who were operated upon for stones might come back because of the reformation of calculi. This reformation was more often met with when the stones had formed in the hepatic or common ducts. For that reason some were inclined to drain the common duct as well, and with reason; stones might be there which could not be felt.

Non-Parasitic Cysts of the Liver and Congenital Cystic Liver.—Dr. WILLIS G. MACDONALD of Albany presented this communication and gave a brief history of three interesting and instructive cases.

I. Cystic Degeneration of the Liver and Kidneys. Associated with Ascites. Aspiration and Drainage. Temporary Improvement.—The patient was a man, 34 years old, who had been four months in the hospital and treated for cirrhosis of the liver. Under local anesthesia the abdomen was opened. After getting rid of a large amount of fluid a large mass was discovered. He removed 6,500 c.c. of fluid of the consistency of molasses, from the tumor of the liver. He tried to attach the edges to the peritoneum, but could not. Two large drains were introduced and sutured to the top and the bottom of the wound. The large cyst involved both lobes of the liver. There were a number of small cysts ranging from the size of an orange to a walnut, forty or sixty in number, which could be seen everywhere. Sudden sepsis developed and the man died with suppression of urine. At autopsy the same condition was found in the kidneys, *i.e.* multilocular cysts. They were enlarged to three times the normal size. Two-thirds of the liver was made up of these cysts, and the liver weighed 14 pounds.

II. Multilocular Cyst of the Liver. Operation, Fixation of the Liver Into Abdominal Wall. Drainage. Recovery.—This patient was a woman, 67 years old, with a large hepatic tumor. When tapped the contents of the tumor was pure mucin in solution. The peritoneum was sewed to the walls of the sac, and the anterior wall of the sac was freely opened. A finger introduced passed into both the right and left lobe of the liver and septa due to pressure necrosis were felt. This patient was drained for two weeks and sent home. After four months the wound had entirely healed. There were no hooklets found in this case.

III. Acute Infection. Local Peritonitis Simulating an Inflamed Gall-bladder.—This case illustrated the difficulties in diagnosis. The patient was a woman, an Italian, from whom but little previous history could be obtained. Two weeks before he saw her she had rigors, fever, pains in the abdomen, and was brought to the hospital under the belief that she was suffering from a distended gall-bladder which had become acutely infected. An oblong tumor was found which rested on the crest of the ilium. When an incision was made the gall-bladder was found to be normal. The tumor was some 15 cm. in length, 7 cm. in width, and 6 or 7 cm. across; it extended from just over and outside the gall-bladder downwards to the right side of the abdomen. It was universally adherent to the peritoneum, the mesentery, and the omentum. It was enucleated with difficulty. By means of a triangular incision the large cyst, together with some healthy liver tissue, was gotten out. The patient was in the hospital a few days, but had no trouble whatever. There were no morphological evidences of hydatids found in this case either. Hydatids cysts were practically unknown in this country.

The Gastric Neuroses.—Dr. DUDLEY D. ROBERTS of Brooklyn read a paper with this title and called attention to the present unsatisfactory classification, its purely symptomatic and accidental character. An etiological classification might be useful, such as the irritation neuroses, direct and reflex, the nutritional neuroses, and the psychical neuroses. These divisions were valuable in the diagnosis of causes of neuroses and in differentiating neuroses from organic lesions. He then spoke of the resulting therapeutic principles.

The Diagnosis and Treatment of Gastric Ulcer.—Dr. DELANCEY ROCHESTER of Buffalo read this paper. He said the diagnosis was very difficult and often impossible, and he gave a brief history of a case, showing how readily a mistake in diagnosis could be made. He never advised operation now unless there was perforation or uncontrollable vomiting. He never saw a case with hypochlorhydria in the so-called peptic ulcer. The symptoms and sings were localized pain, burning or boring in character, increased by the ingestion of coarse fibered foods; sometimes it was colicky in nature. There was vomiting, with the vomit acid in reaction, and containing blood. There was blood in the stools. There was localized tenderness in the epigastrium. The treatment was rest to the stomach, functional and mental, and this could be gotten by the use of atropine and morphine. All foods should be withheld. Continuous application of cold to the epigastrium by means of Leiter's coils was well worth trying. The treatment was directed to the hematemesis and to the ulcer. The latter required a careful study of the

patient to learn the etiology in each case, and included the local treatment of the ulcer and the treatment of the underlying etiological factors. Adrenalin chloride solution was of value. He had also used subgallate of bismuth suspended in a milk of magnesia. Food should be withheld for twenty-four to forty-eight hours. The patient might suck a small piece of ice. Rectal feeding was not advised because it excited an increased flow of gastric juice. One should always study the determining conditions which produced the ulcer, that was, the eye, ear, nose, throat, gall-bladder, pelvic organs, etc. When feeding was given the food should most carefully be selected. Orthoform was another most valuable agent.

Modern Conception Concerning Chemical Regulation of Function.—Dr. GRAHAM LUSK of New York read this paper. He called attention to Bush's experiments with adrenal extirpation, showing that the peculiar conditions produced were not due so much to any injury to the nerve as to the removal of the gland. Adrenalin was a powerful substance which maintained the tone of the system and muscles. The nerve endings must be intact if adrenalin was to be effective. Adrenalin could be heated to the boiling point without injury; therefore, it was not a ferment. With regard to the upper digestive tract, the production of saliva he said was due to a reflex through the nerves. If the vagus in the neck was cut, the vasoconstrictor fibers in the nerve died after three days. Upon stimulation of the still irritable secretive fibers a copious flow of gastric juice would follow. Starling had stated that there were no secretory nerves to the pancreas, but Pawlow said they were in the vagus. The intestinal juice might be stimulated through the nervous pathway; it was a reflex act through the plexus of Meissner. Secretin was caused by the action of the hydrochloric acid; when carried away it caused a secretion in certain localities. Food in the mouth caused a flow of saliva. It aroused a sense of appetite because of a discharge of nerve impulses through the vagus to the stomach, causing gastric secretion. If bread was placed in the stomach through a gastric fistula there would be no secretion; but if the bread was partially digested and then introduced into the stomach through the fistula, the gastric juice would flow. If the stomach was divided into two unequal pouches, bread partially digested, if introduced into the larger pouch, would cause a flow of juice in the smaller. Boiling the pyloric mucosa and pyloric antrum in water and hydrochloric acid, and introducing the filtrate into the jugular vein, would cause a flow of gastric juice. No such effect would follow if the fundus was used. Cannon had found that free hydrochloric acid caused the pylorus to open, while in the duodenum it brought about its closure. Haidenhain showed that hydrochloric acid in the duodenum caused a flow of pancreatic juice. Pawlow believed that the hydrochloric acid acted on the sensory nerves of the duodenal wall and caused a reflex secretion of the pancreatic juice through its effect upon the splanchnics. Dr. Lusk then spoke of secretin and prosecretin, and said that the former could be obtained from almost any portion of the gut. Nerve reflexes were not necessary for the production of the pancreatic juice; it was the result of a chemical excitation through the blood stream. Removal of the bile influenced the digestion of the fats, but not of the carbohydrates. The pancreatic juice contained mother substances of enzymes. Extirpation of the pancreas caused diabetes. Starling had shown that an extract made from the fetus of a rabbit and injected into a virgin rabbit caused the development of the mammary gland; whereas the injection of an extract of the placenta or uterus produced no such effect.

The Effect of Alcohol on the Secretions.—Dr. H. C. JACKSON of Albany read this paper. He discussed the experimental evidence upon the effect of alcohol and the alcoholic liquors upon the secretion of the gastric and pancreatic juice and upon the gastric and pancreatic digestion in *vitro* and in *vivo*. Also the action of alcohol upon the liver and the secretion of bile.

Dr. CHARLES G. STOCKTON of Buffalo believed that chronic pancreatitis was much more common than generally supposed, and it occurred often without having any relation to the bile passages. Its symptomatology should receive more attention. He said he was not quite able to judge to what extent Dr. Ochsner advocated operation in cases of gastric ulcer. His own views were that the operation was not so much for the relief of the gastric ulcer as it was for the results of the gastric ulcer. It was not a question of drainage. One phase of gastric ulcer was often overlooked, the motor function of the stomach. One should realize the importance of spasm in disease. In the treatment of gastric ulcer before and subsequent to operation one should keep in mind not only the questions concerning the amount of secretion of acid, but the importance of feeding the patient, and the spasm of the stomach. He said he had lots of faith in the use of the stomach tube if used with care and with skill.

Dr. ROBERT T. MORRIS of New York said there were two things he would tell a medical student: first, to keep out of debt, and, second, that the cases of supposed stomach and bowel trouble were not cases of stomach and bowel trouble.

Dr. MARY DUNNING of Newburgh asked if there were any satisfactory explanation of the ulcer which followed burns. She called attention to the work of Dr. Margaret Cleaves of New York in the use of trypsin in cancer.

Dr. A. JACOBI of New York said that neuroses of the stomach meant nerve exhaustion. The pain was mitigated by eating; after a few hours the pain returned, to be relieved by taking in of more food. This was not only of diagnostic but of practical importance. When the pain came on two or three hours after eating it meant disease of the colon. In cases of gastric ulcer he said that they should see to it that the stomach was alkaline. Milk of magnesia, and plenty of milk, and milk all the time, together with stale bread, was the best treatment. Under this treatment the patients might get well.

Dr. L. DUNCAN BULKLEY called attention to a case in which the fear of operation stopped gastric digestion.

Dr. JOSEPH COLLINS of New York and Dr. ANGELL of Rochester also discussed the papers.

The Mosquito; Its Relation to Disease and Its Extermination.—Dr. ALVAH H. DOTY of New York presented this paper. It was a review of the literature and of the work done on Staten Island in the extermination of this pest.

A Study of Children Fed on Milk of Tuberculous Cows.—Dr. WILLIAM L. STOWELL of New York read this paper. He said there were 440,000 tuberculous cows in this State. The tubercle bacilli entered the body by the inhalation of air, or locally. The usual portal of entry was by the mouth. Primary infection might be in the intestinal tract. Young animals, including children, were very susceptible to the bacilli. They are likely to receive them in the digestive tract and this meant an interesting relation between the milk of cows and children. New York Infants' Hospital was situated upon an island of sixty acres and there they treated 2,500 patients. Samples of the city milk and the farm milk on the island were submitted to the Health Board every week for examination. It was found that in 1903 the farm milk contained 70,000 bacteria, while the city milk then contained 4,000,000. On the island were more than 28 cows. In December, 1903, two diseased animals were found and killed. The cows occupied modern barns. Each had 782 cubic feet of air space. In October, 1907, the test with tuberculin brought out the fact that out of 30 cattle only three failed to react, and all of them were killed. The three that failed to react were absolutely free from tu

berculosis. Bovine and human tuberculosis was interchangeable. The opsonic index of these hospital children was low and they contracted infections easily. There were 4,537 patients and 180 died; 18 of these died from tuberculosis. This mortality of 10 per cent. in this institution, where the children had been receiving milk from tuberculous cows, was the same mortality as for the nation. He said the milk of tuberculous cows was not so infective as generally supposed. In tracing the history of the children there were no evidences to prove that tuberculosis was more common among those fed on city milk than those on the farm milk, or *vice versa*.

Oxygen in Surgery; A Contribution, with Report of Cases.—Dr. William Seaman Bainbridge of New York gave a brief historical review of the application of oxygen to medicine and surgery. He believed that in surgery oxygen had a most promising field. He gave the results of a series of experiments on animals conducted for the purpose of establishing the influence of oxygen alone and in combination with other elements upon the animal economy. He reported a number of cases in which its therapeutic value had been tested. The oxygen was warmed to 85° or 95° F. and passed from a tank through a hot water bottle and tube into the abdominal cavity. If it was to be used in the thoracic cavity, an aspirating needle was used. He described the technique. The gas was not absorbed in most cases for thirty-six hours. He called attention to the various conditions in which its use should be tried with expected benefit.

Dr. Gwathmey of New York discussed the paper. Oxygen was a remarkable agent for improving the pulse; it had a very good effect upon the heart.

Significance of Uterine Bleeding.—Dr. John A. Sampson of Albany presented this paper, and illustrated his remarks with charts. He gave an analysis of 100 cases where the cause of the bleeding had been ascertained by microscopical examination or subsequent history. Malignant growths caused the bleeding in 28 cases; polyps in 17; threatened or actual abortion in 14; myomata, submucous and interstitial in 13; hypertrophic thickening of the endometrium in 11; laceration of the cervix in 6; ectopic pregnancy in 3; retained secundines in 4; and gonorrheal infection in 2.

Acute Flexures, Angulations of the Sigmoid and Colon.—Dr. James P. Tuttle of New York spoke of the departures from the normal flexures, congenital and acquired. It was the sudden or sharp bending of the gut upon itself which obliterated the caliber according to the degree of the bend. There were anatomical bendings throughout the colon which served the purpose of retarding the fecal currents. If these are exaggerated the amount of obstruction was increased. The more the transverse colon descended the more was the obstruction, an important factor in enteroptosis. A shortened mesentery might cause a narrowing or obliteration of the intestinal caliber. He described the conditions he had seen and operated on. In 1897 he pointed out this condition and he operated upon seven cases up to 1902. Dr. Tuttle reported cases and illustrated his remarks by pictures. There was one important symptom, upon which he had been able to make a snap diagnosis. When the patient took an enema of any fluid and went to stool, he went several times to get rid of all the fluid. This applied to the acute flexure cases. The treatment was palliative and radical. In some cases of the acquired type pneumatic inflation with a soft rectal bougie through the flexure was done and the bougie left in. This tended to straighten out the gut and gave a straight passage for the fecal matter. If kept up for months this gave great benefit. Always do this through the proctoscope in order to see the aperture, and then push the bougie through. Otherwise it would bend. Before removing it he injected oil. If this treatment failed the condition was due to malformations or fixations and the operative interference varied in each individual case.

Aërotherapy in Certain Toxemias of Childhood.—Dr. Frederic W. Loughran of New York said that aërotherapy had long been practised, but not until the last few years had it been raised from a fad to scientific fact. Its application had done much to simplify treatment, to lessen the period of acute illness, to shorten convalescence, and to avoid drugging.

Vascular Crises.—Dr. Henry L. Elsner of Syracuse said that the object of his paper was to emphasize that arteriosclerosis might exist many years without a single objective symptom; that sensory symptoms, paroxysmal in character, often of serious import, were due to vascular spasm. He defined vascular crises, and considered the evanescent symptoms referable to various parts of the body in connection with vascular crises. In young subjects arteriosclerosis was very likely to lead to death, or to serious complications, without delay. Conditions heretofore misinterpreted were considered in connection with vascular spasm as a cause. He called attention to the fact that there was an abdominal angina and a coronary angina, and that both might alternate with each other. In pure angina pectoris the pain might be referred to the abdominal organs. This was something that should not be forgotten. Improvement by treatment would improve, but not cure. The great danger lay in the fact that Nature brooked so many insults that revolt was too long postponed to admit of final reparation.

The Causes and Treatment of High Arterial Tension.—Dr. Louis Faugères Bishop of New York read this paper. He said that high arterial tension was the result of physiological reaction to pathological conditions. The causes were found in the circulatory system itself, or outside of the circulating system. He referred to the relations between the composition of the blood and the blood pressure. When we considered the causes of high arterial tension in relation to the recent increase in its dire results, the one that most interested us was to be principally found in the wide prevalence of hypertonia vasorum of nervous origin. After describing the instrument that he had devised for quickly ascertaining the presence or absence of high or low arterial tension, he said that the early detection of high arterial tension was very important in connection with treatment, because this was reflex from some underlying cause. The first step in the treatment of a case was to determine exactly the condition of the various organs, and symptoms should be corrected. The diet, exercise, environment must be properly selected, and the patient should be managed over a sufficient length of time for the correction of underlying causes and the completion of a physiological reeducation which might overcome the high tension habit.

Dr. A. Jacobi of New York said that arteriosclerosis commenced normally at about the age of 35 years; that it did not begin uniformly, for in some it began in the kidneys, in the brain, in the periphery, etc. So long as it did not affect the brain, the man would be of some use in the world. He advised the examination of the urine in every case of man or woman over forty years old. It was not ever right to state that if there was only a slight trace of albumin present, that urine was a normal one. Seldom did arteriosclerosis appear unless associated with Bright's disease. In cases of arteriosclerosis something could be done for the patient. The nitrites were in order, but he believed in giving a diet which contained less of the calcium salts than was generally given. Also some medicine which was known to influence the deposit of lime, especially the lactated alkalies and lactic acid.

The Diagnosis of Pulmonary Tuberculosis by Tuberculin and Other Tests.—Dr. Lawrason Brown of Saranac Lake said that pulmonary tuberculosis might be a

disease mainly of symptoms or of physical signs. The symptoms were usually the first indications. It was dangerous to wait until the tubercle bacilli occurred in the sputum; they never occurred until there was an ulceration of parts of the lungs. The examination of the feces for tubercle bacilli was often of value. Physical signs might appear without any symptoms. He offered some practical points in making physical examinations. One was to tell the patient to breathe out, to cough and then breathe in; in this way one could get ralés that could not be gotten in any other way. More attention should be paid to the condition of the apices. When all other methods of diagnosis had been exhausted, then and not till then, should recourse be had to tuberculin. It had about the same value in tuberculosis as had the Widal in typhoid fever. The ophthalmic test would probably prove of great value.

Esophagoscopy and Bronchoscopy.—Dr. THOMAS H. HALSTED of Syracuse presented many instruments and reported some cases.

A Study of Three Hundred Cases of Acute Anterior Poliomyelitis Occurring in the Recent Epidemic in New York City.—Dr. JOSEPH COLLINS and Dr. THEODORE H. ROMEISER made this report. This epidemic in New York began in July and practically ended in October. There were probably as many as 1,200 or 1,500 cases in this epidemic in New York and its suburbs. As a result of the prevalence of this disease much absolutely new had been learned. Hitherto clinicians and neurologists relied upon information received a long time after the disease originated. Not one neurologist in New York had ever seen a case during the time of its occurrence. With regard to the curability of the disease the books had stated that the disease was never recovered from. In this epidemic one case in 10 or 11 made a good recovery, and about one in 20 absolutely recovered. In this epidemic not only were the anterior horns of the spinal cord involved, but the disease affected other portions of the cord, and even extended up into the medulla and the pons, into the substance of the gray matter around the ventricles and into the cortex. The muscular paralysis was not confined to the extremities; paraylsis occurred in the abdominal, the lumbar and facial muscles as well. There were 202 males and 114 females affected in their records. The dangerous age was between one and three. The youngest patient was four days old, the oldest 15. Vomiting, constipation, anorexia, or thirst occurred in 114, diarrhea in 11, and aneuria in 21. The distribution of the paralysis showed one leg involved in 104 cases, both legs in 59 cases; one arm in 12 cases; both arms in 1. The abdominal muscles were involved in five cases. The early treatment was *rest*. After the subsidence of the inflammatory process the limbs should be placed in such a position that will entail less dragging and less deformity. It should be remembered that the pathological condition continues for days and weeks even after the acute manifestations have subsided and rest must be enforced. The importance of massage was brought out. Electricity was of value, but no more a specific than in other disease. Large doses of strychnine intramuscularly were of great value.

Officers Elected.—*President*, Dr. Edward L. Trudeau; *First Vice-President*, Dr. Arthur G. Root; *Second Vice-President*, Dr. John T. Wheeler; *Third Vice-President*, Dr. M. C. Hawley; *Secretary*, Dr. Wisner R. Townsend; *Treasurer*, Dr. Alexander Lambert.

Thursday, January 30—Third Day.

County Laboratories and Their Uses.—Dr. ORLANDO J. HALLENBECK of Canandaigua read this paper. He said that a fifteen months experience with a typhoid fever epidemic in an asylum had impressed him that we had inadequate means of fighting the enemy. The State laboratory was too remote. In order to prevent the dissemination of this and similar diseases, county laboratories should be provided. He said he was convinced that if every county in the State had a laboratory, it would be a great investment for the taxpayers. The disease was spread through the latent cases, and such diseases as typhoid could be positively diagnosed if means were at hand. Having been convinced that the health and the happiness of the citizens in the county depended largely upon this, he brought the subject up before his friends to get their support and cooperation. A campaign of education was at once started. At the regular meeting of their medical society in January, 1906, a committee of three was appointed to proceed along certain lines of providing ways and means of establishing a county laboratory. The Ontario County Medical Society also appointed a Committee. These committees formulated a plan to bring about the desired result. The citizens of the county were to be the beneficiaries and they should bear the expense. This meant money for the taxpayers. A citizen of Canandaigua donated enough money to erect and equip a house with the proviso that the State donate enough money to hire a pathologist and bacteriologist. For this purpose $1,500 were asked for. Charges were to be made for services rendered outside the county. It was further planned, if the project was a success, to organize a sanitary association, and the executive committee of this association would have general supervision of laboratory, etc. It was found, however, that the Board of Supervisors had no control. Then they interested the Senators and had an act passed which enabled the Board of Supervisors to act in the matter, and also to give the money annually for the pay of a bacteriologist. In 1906 the Sanitary Association was organized. The county laboratory was now a fact and was running on a paying basis. They had a first class bacteriologist and pathological laboratory. This was in a county of 50,000 population. The expenses for the first fifteen months was $111.91; receipts were $163.00, leaving a balance of $51.09. He asked that the Society appeal to the Governor, the Senators and the Assemblymen for power to equip such laboratories in every county in the State.

Dr. ROBERT P. BUSH of Horseheads asked that immediate action be taken on this matter. He said he had been appointed to confer with the Board of Supervisors and, as the result, a bill had been introduced which would give the Board of Supervisors power to act. The question was, should this bill affecting but one county be pushed, or should another bill be introduced which would affect all the counties.

Dr. HUBERT SCHOONMAKER of Clifton Springs said he had visited the Canandaigua laboratory, and he had no doubt but that the existence of such a laboratory in the county had an uplifting influence on the profession from the standpoint of medical science. By virtue of its presence it created a better scientific atmosphere. He was sure the County of Ontario was to be congratulated.

Dr. A. JACOBI of New York said that he was positive that if every member of the Legislature had a copy of the paper, no member could resist the request. He believed that a resolution, accompanied by a printed copy of the paper, placed in the hands of each member of the Legislature, would be a power in aid of the passage of the bill. He asked that some resolution be formulated and the resolution given over at once to the Council for further action.

Such a resolution was moved, seconded, passed, and sent to the Council.

Intracranial Complications of Middle-Ear Suppuration with a Report of Ten Cases Under Observation in Eighteen Months.—Dr. S. J. KOPETZKY read this paper and offered the following summary: 1. That intracranial complications result from contact of diseased bone with the dura, or they come about from an invasion of the

cranium through the labyrinthine or other anatomical channels. 2. That trauma, either accidental or surgical, may arouse into activity a latent intracranial lesion. 3. That intracranial lesions are generally, although not invariably, the result of an engrafted acute process upon a chronic middle-ear suppuration, especially if the chronic suppuration is a disease of the bone. 4. That intracranial invasion, when located in the posterior cranial fossa, will first have involved some part of the labyrinthine channels. 5. That involvement of the middle cranial fossa is more amenable to surgical treatment than when the posterior cranial fossa is the seat of the lesion. 6. That the earlier the surgical intervention, the better the prospect of an ultimate recovery. 7. That the evacuation of the pus from the posterior cranial fossa without surgical relief of the purulent labyrinth is useless (when the labyrinth is involved). 8. That lumbar puncture as an aid to the surgical treatment is of no value. 9. That no case should be considered too hopeless to submit to operation, as sometimes surprisingly good results are obtained even in such. 10. Finally that the surgical trauma in the form of radical mastoid operation should be imposed only on a patient giving the positive diagnosis of bone necrosis. Mastoid operation should not be undertaken simply to attempt a cure of a persistent purulent otorrhea.

Chronic Middle-Ear Deafness.—Dr. W. Sohier Bryant of New York read this paper. In his opinion there are very few cases of chronic middle-ear deafness that could not be improved. The exceptions are the cases of malformations of the middle-ear, the cases of advanced stapes fixation, and those of extremely advanced otosclerosis. The amount of the possible improvement in hearing is in inverse ratio to the pathological changes. Chronic deafness from past or present suppuration of the middle-ear can, without exception, be helped by treatment. The amount of help depends upon the power of the patient to make repair and upon the power of the physician to substitute parts which have been lost. Dr. Bryant stated that the causes of chronic middle-ear catarrh arose in the nasopharynx and affected the middle-ear by interfering with the Eustachian tube. The aim of treatment was first to restore the function of the Eustachian tube, and second to correct the defects of the middle-ear. By the treatment of the nasopharynx, prophylaxis of these defects was easily secured. He further stated that the causes of stapes fixation were trophic disturbances. Not only must these disturbances be checked but their recurrence must be prevented. The chief difference between the etiology of middle-ear suppuration and chronic middle-ear catarrh was pyogenic bacterial infection. Suppuration occurred almost never independent of nasopharyngeal disease. Prophylaxis of chronic middle-ear deafness due to suppuration was secured by preventing purulent inflammation through the care of the nasopharynx. But if suppuration had already begun, the hearing was preserved by immediately stopping the suppuration and by treating the nasopharynx appropriately. If any suppuration should exist in chronic middle-ear deafness, it must be immediately arrested. If perforations of the membrane existed, they must be closed by the growth of cicatrices. In order to compensate for the important parts of the sound conducting mechanism which might have been lost, it was necessary to adjust mechanical appliances. Adhesions of important parts must be loosened. He reported in brief, twenty-four cases. One showed a good improvement in hearing in a case of stapes fixation. Nine showed the three conditions caused by chronic middle-ear deafness treated in nine different ways with success. Thirteen showed thirteen various forms of chronic middle-ear catarrh treated in various ways with good results. The principle of this treatment was stimulation, exercise, and removal of tubal obstructions. Dr. Bryant concluded that all forms of chronic middle-ear deafness, except the congenital, were amenable to treatment, and that the amount of improvement justified the effort expended.

Medical Libraries for the Smaller Centers.—Dr. Smith Baker of Utica read this paper. He said that in nearly five hundred incorporated villages in the State of New York and all but seven of its cities there was not a Medical Reference and Circulating Library yet to be found. The physicians and surgeons purchased their own books and periodicals, etc., and such of course necessitated a useless duplication of professional works and periodicals in each community and this not only wasted funds, but resulted in one being inadequately provided for. The first medical library in this country was founded at the College of Physicians in Philadelphia in 1721. He urged that anything this organization could do to stimulate the inception and growth of Medical Reference and Circulating Libraries among all centers, large or small, should be ungrudgingly and persistently rendered. The idea itself needed advertising, encouragement, and enlightening. The State Library at Albany should be encouraged to stand in helpful relation to these enterprises.

Technique of an Efficient Operative Procedure in Malignant Disease of the Skin.—Dr. Samuel Sherwell of Brooklyn read this paper. He said he did not claim novelty as to method nor absolute perfection as to result, but he had used the method for thirty-five years with good results and relatively few recurrences. He recommended simply curettage, but thorough, deep, and efficient, followed by immediate and thorough application of an escharotic, preferably a 60 per cent. solution of acid nitrate of mercury. The caustic agent must be neutralized by some alkaline medium; he preferred common sodium bicarbonate in powdered form. This formed a scab which was allowed to remain till it fell or was pushed off by process of repair beneath. He said the scar was relatively insignificant. The knife was perhaps preferable in pendant and loose portions of the body—as penis, lips, ears—but in many of these even he preferred the method here described. He objected to the *x*-ray and radium because of time, expense, and uncertainty of result. He seldom found it necessary to use general anesthesia. The curette used should have a clean wire edge. He preferred oxide gas where general anesthesia was necessary. The amount of touching with acid nitrate could be learned only by experience; he frequently allowed it to remain ten to twenty minutes before neutralization. The last step was the introduction of bicarbonate of sodium into the excavated surface, pressed firmly down to make an adherent scab. This turned yellow and later black, and usually came off in a fortnight to three weeks. It should be kept dry. He did not use bandages. Inflammation followed at site after a day or two, but no dressing, and particularly no wet dressing, must be used. It would soon go down. The chances of recurrence were far less than after the use of the knife.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK

Special Meeting, Held on January 6, 1908.

Dr. Nathan B. Van Etten, Chairman for the Borough of the Bronx, in the Chair.

On Some Newer Aspects of Cardiac Pathology.—By Dr. Thomas E. Satterthwaite. The author, after stating that we had now reached a point where we could say with confidence that all toxemias, acute or chronic, some dyscrasias and hyperpyrexias, if long continued or severe, as well as other conditions, produced definite morbid changes in the heart walls, evanescent or permanent, said that while it had been difficult, of course, to connect characteristic clinical phenomena with each particular change, even that had been done with such a degree of ac-

curacy that, although we were lacking in important pathognomonic signs, we still were able to form in our minds tolerably distinct pictures of the several myocardial affections in their several stages. The word myocarditis had led to much misapprehension. It had been and still was used somewhat indiscriminately for various myocardial diseases. To most of us myocarditis implied myocardial inflammation, and therefore did not include the degenerative affections of the organ. Dr. Satterthwaite offered a new classification for these diseases, as follows: 1. Acute parenchymatous myocarditis. 2. Acute diffuse myocarditis, including the tuberculous, syphilitic, and suppurative forms. 3. Chronic myocarditis, including all the diffuse inflammatory changes mentioned. 4. The fat heart. 5. The fatty heart. 6. Hypertrophies, whether due to severe exercise, vascular diseases, blood disorders, neurotic disturbances, or possibly to pregnancy. Dilatation was not enumerated as a disease; it was an incident occurring at times in any of the varieties mentioned, and could not, therefore, be classed by itself. Some such classification as the above was essential for a clear conception of myocardial diseases, although many of the pathological phenomena were apt to be interconnected in any single instance. In considering the morbid changes of the tissues, the speaker stated that, so far as the parenchymatous alteration was concerned, it was the earliest form of muscle metamorphosis. The early parenchymatous changes were probably analagous to the "cloudy swelling" that many pathologists believed was the initial sign of nephritis. Acute myocarditis might occur in rheumatism with or without the articular signs; it was found also in tuberculosis, tonsillitis, measles, lobar pneumonia, erysipelas, epidemic influenza, septic processes, and gonorrhea. The parenchymatous change might be localized or general, usually the latter. Seen with the naked eye, the muscle tissue was lighter colored than normal, while the cut surface was lack-luster in appearance, swollen, and moist. Microscopically, the muscle cells were enlarged, less translucent than usual, and studded with minute particles derived from the protoplasm of the cells and albuminoid in character, so far as chemical tests showed. According to our present ideas, these changes were due either to the toxins of the above-mentioned diseases or the continued fever. In alcoholism a similar condition had been noted, though in that instance the alcohol was probably the poison. The mechanical effect of this change was naturally to limit the contractile powers of the muscle and cause cardiac debility sooner or later, so that the pulse was increased in frequency in order to maintain the equilibrium of the circulation; and yet if the nervous system was affected, as in diphtheria or uremia, the pulse might be abnormally slow. So far as the prognosis was concerned, we had to assume from analogical reasoning, together with clinical experience, that parenchymatous change, if not excessive, might disappear with convalescence; and yet, by analogy, we might equally well hold that they could lead up to acute diffuse myocarditis, and might terminate in fatty denegeration also. In most cases, however, we knew that the patients recovered wholly, so far as we could determine by clinical tests.

Instruments of Precision in the Management of Diseases of the Heart.—Dr. Louis Faugères Bishop said there were three elements to be considered in the treatment of circulatory diseases, each of which had its appropriate instruments of precision. These were the heart itself, the blood-vessels, and the circulating blood. The first to be mentioned, but not least of importance, was the hemoglobinometer, since the quality of the circulating blood had a profound influence upon the course of circulatory disease. More often than one might suppose the blood was found with a too great richness of hemoglobin, and with the red cells above the average normal number. For that reason accurate and frequent examination of the blood was of importance in the management of cardiac disease. Next should be mentioned the use of the blood-pressure measuring apparatus to estimate the pressure of blood in the arteries. This was never to be separated from the skillful palpation of the pulse, nor must one be misled into a false sense of safety by a normal blood-pressure. The mechanism by which the blood-pressure was regulated was able to maintain pressure within normal limits until changes in the heart and blood-vessels of an organic nature might have proceeded to a great degree of development. High blood-pressure was the result of cardiac energy acting against blood-vessel hypertonicity, and was never to be considered apart from the condition of the blood-vessels. The speaker referred to the great importance of vascular overtone as an element to be treated in many cases of heart disease. This overtone was chiefly discovered in the pulse, and was accompanied by high blood-pressure and certain cardiac and nervous symptoms, often leading to the belief in the existence of neurasthenia and heart disease. Its presence was proven by the course of the case and by the almost magical effect of a suitable plan of treatment. The sphygmograph was an instrument of record rather than one of precision in diagnosis. After showing the blood-pressure apparatus designed by Dr. T. C. Janeway and the Riva-Rocci instrument, Dr. Bishop demonstrated a method of estimating blood-pressure with which he was experimenting by the direct use of water pressure.

The Diagnosis of Diseases of the Heart.—Dr. William Henry Porter, in this paper, stated that one of the most important points to be considered was how to recognize and correctly interpret the so-called valvular murmurs. This was especially true in view of the fact that we had well-defined murmurs when there was no endocardial lesion of the valve and at the necropsy the valves were found to be practically normal. In order to accurately diagnosticate these valvular affections of the heart it was absolutely essential to understand precisely the anatomical position of the organ, and also the physiological mechanism of the action of the heart. A common law governed the seat and transmission of all cardiac murmurs, to wit: The abnormal sound called a murmur was heard with greatest intensity just beyond the point of its development, and the sound was transmitted from this point forward or backward in the direction of the current of blood, which, together with the valvular defect, was the cause of the murmur. Where there was an organic narrowing of the bicuspid orifice, an abnormal sound was produced in the line of the left auriculo-ventricular axis by an obstruction to the normal incoming current of blood from the left auricle to the left ventricle. This murmur had often been called presystolic, which was true so far as the ventricle was concerned, but in reality it was a systolic murmur of the left auricle. It occurred at the height of or just at the end of the auricular contraction, and just as the ventricle was beginning to contract. A mitral direct murmur was heard with greatest intensity just in front of or over the left ventricle at a point where the left auriculo-ventricular axis struck the anterior surface of the chest wall, over the junction of the fourth rib and its adjoining costal cartilage. This murmur was as a rule high-pitched, of short duration, and usually limited in area. The intensity of the murmur varied with the degree of obstruction and the strength of the auricular contraction. An obstructive murmur, located at the left auriculo-ventricular orifice, without any alteration in the structure of the mitral valve, was not infrequently heard in connection with considerable leakage at the aortic orifice. Regurgitation at the mitral orifice, without organic changes in the valve segments, unquestionably produced a mitral indirect murmur, and one which was of the greatest importance, first, because of its frequency; second, because it was so often

mistaken for a sound due to positive organic changes in the valve segments. Organic and the so-called functional insufficiency at the left auriculo-ventricular orifice could easily be differentiated during life, not by their rational or physical signs, however, but by an appropriate line of treatment. When the physical signs were due to positive lesions in the valve segments, then they would not disappear, but would usually become more pronounced under treatment, even though the general condition was improving. The abnormal sounds developed at the aorto-ventricular orifice were best divided into three general classes: 1. Those due to organic changes in the valve segments and the aorta, or in the substance of the ventricular wall as a whole. 2. Those due to congenital perforations of the segments of the aortic and pulmonary valve, and which might be classed as functional when compared with the truly organic changes that were acquired. 3. The so-called hemic murmurs. A positive diagnosis in cardiac conditions should only be given after several examinations, and after suitable treatment had been instituted. Hemic murmurs, so-called, were produced at the aortic and mitral orifices in very anemic subjects, and might be of the direct or indirect variety. A tricuspid direct or indirect murmur was practically an impossibility, owing to the almost negative blood-pressure on both sides of the valve.

On the Use of Drugs in Diseases of the Heart.—Dr. Reynold Webb Wilcox said that the wave of therapeutic nihilism which had of late years affected the profession was happily now passing away. Substitution and failure to observe the requirements designated by the United States Pharmacopœia were punishable by severe penalties, so that reliance could be placed on the quality of the remedies at our disposal. The work of the heart was determined to a very large extent by the condition (1) of the vessels, (2) of the cardiac walls, and (3) of the valves, the last-named being less important than the others. After referring to the value of the hemoglobinometer, the sphygmograph, and the sphygmomanometer, Dr. Wilcox expressed the opinion that the question of the blood-pressure was as yet only in its infancy. We could regulate the rapidity and the force of the heart's action, and there were three groups of remedies at our disposal for accomplishing this. As long ago as 1783 Withering had correctly laid down the indications for the use of digitalis as a rapid, low-tension pulse, with venous congestion. It was indicated, in general, when the cardiac action was rapid and feeble, with low arterial tension, and it was contraindicated when the cardiac action was strong and arterial tension high. Digitalis, however, had its defects, and the principal of these was the pronounced vaso-constriction which it produced. This led to the study of strophanthus as a substitute for it in suitable cases. This drug was found to be less of a vasoconstrictor and to have a more rapid action, and experience had shown that it should be used in the place of digitalis in the case of children and of the aged. Convallaria was untrustworthy, and adrenalin, another drug of the digitalis group which was now official, was objectionable on account of the renal irritation which it caused. Erythrophleum, or sassy bark, the last of the five drugs of this group, was a remedy which slowed the pulse and raised the tension, just as digitalis did. He had made a careful study of its effects, and the results obtained in the laboratory were confirmed by clinical observations. As compared with digitalis, it was decidedly more active in slowing the pulse, but it was irritating to the stomach. As a vaso constrictor it had greater effect than digitalis; in fact, as great as digitalis and ergot combined. While it was less cumulative than digitalis, it was also rather less reliable. Its use, he thought, should be confined to those cases of fairly competent heart with low vascular tension, in which it would show its effects more rapidly and markedly, and to those cases in which digitalis had lost its usefulness or had entirely failed. In the recent revision of the United States Pharmacopœia the tincture of strophanthus and all potent tinctures had been placed at the uniform strength of 10 per cent. The speaker next discussed the class of drugs which weakened the heart's action and slowed its rate, such as aconite and veratrum. Both of these were of great value in appropriate cases. Veratrum was especially esteemed by the obstetricians, and the danger from its use had been much exaggerated, since it always gave ample warning when it was being carried too far. There was only one drug which both increased the force and frequency of the pulse, and that was cactus. It was especially useful in neurotic heart and slow heart. If an active preparation was used, and such was readily found in the shops, brilliant results were obtained in appropriate cases. In pulmonary edema with heart failure the speaker did not know of any remedy as good as hot coffee given by high rectal injection. By combining with each dose half a grain of caffeine sodiobenzoate, we could get along with much less digitalis than otherwise. Strychnine was sometimes of service in cardiac disease, but one difficulty with it was that patients readily became habituated to its use. As to cardiac syphilis, he recalled three cases of gumma of the heart, proven to be such in the dead-house. In this disease he had found that arsenic iodide had sometimes proved efficient in cases in which the usual antisyphilitic remedies had entirely failed.

Dr. Satterthwaite asked the opinion of Dr. Wilcox of the value of adrenalin in cardiac failure.

Dr. Wilcox said that Dr. William H. Bates was the first to demonstrate the effect of suprarenal extract upon the eye and the larynx. He himself had been the first to make sphygmographic tracings under dry suprarenal extract, and these corresponded very closely with those obtained with adrenalin later. He thought that adrenalin should be employed for shock only when this was due to dilatation of the blood-vessels of the splanchnic area. Unless great caution was employed in its use, a weakly acting heart might be overwhelmed.

Dr. Satterthwaite said he had heard of cases in which death was caused by adrenalin. Under its use the pulse ran up very high at first, but soon sank below normal, and he therefore regarded it as a very dangerous drug. On the other hand, he had found the suprarenal extract distinctly useful at times, and he was accustomed to employ it in appropriate cases.

Dr. Edward E. Cornwall of Brooklyn thought the water sphygmomanometer of Dr. Bishop was very ingenious but unlikely to prove of much practical use on account of the height of the ceiling required, to say nothing of the step-ladder. As for the therapeutic nihilists to whom Dr. Wilcox referred, he was inclined to doubt if they existed to any important extent among regular physicians. He had never known of any excepting among Christian Scientists and the like, and he was inclined to believe that therapeutic nihilism was a bugaboo invented by those who were in the habit of using drugs excessively and without clear indications. These, whom he thought constituted a very numerous class, he suspected of stigmatizing the advocates of conservative and rational therapeutics as therapeutic nihilists in order to distract attention and criticism from their own prejudiced therapeutics. The speaker said he was pleased with Dr. Wilcox's remarks on strophanthus; he used the drug extensively and had learned to value it at least equally with digitalis. He thought its range in cardiac therapeutics was greater than that of digitalis, and though not exactly co-extensive, included much of the rangs of digitalis. He had found by clinical experience that for restoring lost compensation in valvular disease in children it was better than digitalis, and in conditions of high blood-pressure and in

dilated hearts with greatly weakened myocardium he thought there was no question of its superior value. He believed that failure to get good results from its use was often due to the fact that it was given in too large doses. He had observed clinically that while it was generally much less irritating to the stomach than digitalis, there were a few people who received less therapeutic benefit from its use and more irritation of the stomach than they did from digitalis. In regard to cactus he was inclined to believe it was a cardiac sedative of value in functional disorders. Convallaria he had found so vastly inferior to digitalis and strophanthus that he seldom used it. He thought we could well afford to ignore the claims of sparteine while we had so many better ones.

Dr. Robert E. Coughlin of Brooklyn said that for a number of years he had been interested in the subject of myocardial disease as related to athletes, and the strain put upon the heart in athletic contests. As medical men we were not particularly interested in the professional athlete, only so far as his life might become an example to the growing young, many of whom sought our advice when about to enter into athletics. The subject was very important when we considered that young school boys were at present put into contests by the public school instructors when their hearts were subjected to a very severe strain, as in sprinting and running a distance. There was great chance of injury being done the heart by violent exercise in competitive games. His opinion was that the young probably exercised too much, and those over 40 and 50 not enough. Hanlon, the famous oarsman, died at the age of 52 after a two days' illness of pneumonia, and it was known to be a fact that he had taken no exercise for ten years prior to his death. Was it not reasonable to suppose that after such an interval of inactivity myocardial disease was really the cause of his succumbing to pneumonia, which so markedly taxed the heart? Persons over 40 should try to keep up their cardiac muscle, so that no degeneration took place; this was especially so in men who had overdeveloped their cardiac muscle.

Dr. Porter, in closing, said he was glad that the question of the so-called athletic heart had come up for discussion, as it was very important, and, like all other affections of the heart, required a clear conception of the laws governing the nutrition of the heart muscle to fully understand. The one thing to be remembered was that the nutrition of the heart and all the tissues of the body depended upon a uniform expansion and contraction of the ultimate arterioles, so that the blood could be passed slowly or rapidly through the arterial capillaries, at which point all nutritive interchange occurred and was regulated, according to the demands of the tissues. By destroying this peculiar physiological control, the varying forms of pathological lesions were brought about. In the athletic heart, in consequence of great exertion, there had been a large demand for nutritive material by the muscle fibers, and they underwent physiological hypertrophy at the expense of the intermuscular connective tissue. Stop the exercise and the muscle fibers atrophied, but without corresponding hypertrophy of the intermuscular fibers. Hence, a weak heart resulted, the cavities dilated, and sudden death often occurred without apparent reason. The tension of the arterioles was the all-important element in the production and treatment of diseases of the heart. If the high or low tension was due to a toxemia from putrefactive fermentation in the intestinal tract, we must direct our remedies in such a manner that this causative factor would be removed. If the cause was an incompetent liver action, this must be sought out and relieved. If the fault was in the kidneys, they must be the organs to receive first attention. In like manner, if the faulty action was centered in the nervous mechanism, it must be the first point for our therapeutic attack.

Medical Items.

Pigmented Moles and Warts should either be left entirely alone or else completely extirpated with the scalpel. Protracted irritation by the application of caustics, curetting, etc., may lead to the foundation of new growths.

Abdominal Tumors.—Tumors of the liver, spleen, and stomach generally move freely with respiration as distinguished from tumors of the pancreas and kidneys, which move less freely.—*Southern Medicine and Surgery.*

Appendicitis in the Nursing Child.—Henri Mayet says that appendicitis is rare during the first year of life, but that it exists and should be looked for in the course of intestinal troubles. It is never present alone, but is a complication of severe forms of enteritis. In all the recorded cases, which amount to only nine in all, there was present severe enteritis or obstinate constipation. It is to be feared when in the course of an enteritis the abdomen becomes swollen, the muscles tense, the temperature and pulse high, and the percussion note is modified in the right iliac fossa. The age of the patient prevents other localization of the painful symptoms. Flesh eating cannot be given as a cause in nursing children; foreign bodies have not been found at autopsies, and the author refers the disease to enteritis as an exciting cause. Appendicitis is apt to occur in emaciated, cachectic, or rachitic children who are predisposed to any complication. The appendicitis is simply a localization of the enteritis. The prognosis is very bad, since the peritonitis is of the fulminating variety, and death occurs in from one to four days, provided the condition is not relieved by operation at once. In children over one year of age the course is much more mild and the prognosis better.—*Annales de Médecine et de Chirurgie Infantiles.*

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service for the week ending January 31, 1908:

SMALLPOX—UNITED STATES.

WHAT SHALL WE DO WITH FAR ADVANCED CANCER OF THE LARGE BOWEL?*

BY R. C. COFFEY, M.D.,

PORTLAND, OREGON.

PRESIDENT OF THE OREGON STATE MEDICAL ASSOCIATION; SURGEON-IN-CHIEF TO THE NORTH PACIFIC SANATORIUM.

WE may divide far advanced cancer of the large bowel into three classes: (1) Those which are far advanced from a functional standpoint but which are not far advanced by reason of the extent of the

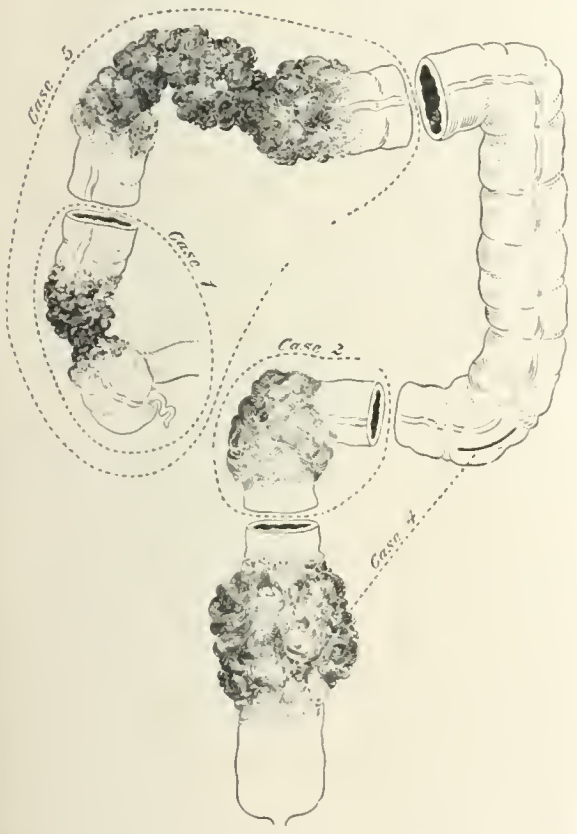

FIG. 1.—Showing the extent of operation in the several cases indicated.

involvement. A type of this form is seen in the annular variety which early produces a stricture and total obstruction. (2) Those in which obstruction is present, due to an extensive growth in one side of the intestinal wall and in which there is marked cachexia. (3) Those in which a growth is extensive in the proximal wall and mesentery, producing marked cachexia without obstruction. Unfortunately, it so happens that most cases of cancer of the large bowel, when they reach the surgeon, belong to one of the three varieties of the far advanced cancer. Those cases of cancer of the large bowel which are diagnosed early, before any of the foregoing conditions exist, admit of no discussion as to the proper treatment, as I think it will be conceded by all authorities both medical and surgical, that early operation is the thing to be done. Such unanimity of opinion does not exist as regards the far advanced cases. Hence the question asked in the title.

The subject of cancer is at the present time receiving the attention of a great many writers and investigators, and it is well that such should be the case, for, according to government statistics as classified by McConnell, in 1890, cancer was thirteenth in the list of causes of death, and the death rate was 47.9 per hundred thousand of population. In 1900 it had moved up to seventh place in the cause of death to the death rate of 60 per hundred thousand of population. It is especially interesting to us on the Pacific Coast when we learn from the same authoritative source that our Pacific Coast country has a larger per cent. of cancers than any other part of the United States. For we find that the Pacific Coast region has 51.9 deaths from cancer in every thousand deaths, while the heavily timbered northwest region of Minnesota and Wisconsin follows closely with 46.8; the prairie regions with 43; the central regions, plains and prairies, 34.1; the gulf coast and south Appalachian section, 20; while the southern Mississippi river belt gives only 11.3 deaths in a thousand deaths. I personally do not like to contemplate that our country is the very worst for this most serious of all diseases, and would be inclined to try to explain it on the ground that our extremely healthy climate produces fewer deaths from other causes and therefore increases the proportion of cancer. One of McConnell's conclusions is that cancer appears to have actually increased in the United States, 12.1 deaths per hundred thousand of population, or about 25 per cent., in the last ten years. This seeming increase may be more apparent than real, as our diagnostic methods may reveal many internal cancers that were formerly not diagnosed either before or after death. This condition is even more alarming when we remember the fact that so far absolutely nothing has been determined as to the cause and nature of this malady and nothing except early and complete extirpation offers any hope of cure. This, the only treatment, is made impossible in the majority of cases, first because the people do not appreciate the dangers of apparently minor symptoms or, being in dread of having a surgical operation performed, willfully avoid physicians; or, because of the well-known tendency of cancer to recur, they refuse to have the knife used lest (as they believe) the cancer be thereby stimulated. Second, many physicians, in deference to the public, lest they should be classed as alarmists, watch a suspicious growth for a long time and thus postpone

*Read at the annual meeting of the Oregon State Medical Society, July 13, 1907.

action till long after the case should have been in the hands of a surgeon; but a very large percentage of cancers produce such slight symptoms and are in such protected places in the body that the most expert diagnostician may be misled until radical cure is impossible. Cancer of the large bowel, because of the protected positions which it occupies, and because of the extreme difficulty of reaching some portions of it for surgical purposes, has been more unsuccessfully treated and therefore has received less attention until recently than has cancer in other parts of the body. Within the past two or three years, however, interest has become greater in this subject and consequently success has been better. At the Cleveland meeting of the American Surgical Association (1906), articles were read by C. H. Mayo, Bloodgood, Armstrong, and Willy Meyer, and in August, 1906, published in *Surgery, Gynecology and Obstetrics,* which symposium I believe is our best treatise on the present status of the treatment of cancer of the large bowel. But we are just opening this field of surgery and it is for this reason that I present this paper, based on an experience covering one year, and relating all the cases treated by me during that time, giving the stage and extent of the disease, form of treatment used, and the immediate results of the treatment.

As I have stated in a previous paper on appendicitis, statistics are so unreliable, depending entirely on the viewpoint of the maker of the statistics, that they are of little value to any one else, unless the circumstances of each case are related and unless all the cases coming in the practice of a given operator are reported as they occur. For instance, one operator may take the position that no attempt at operation should be made unless a positive assurance of permanent cure be given. This operator, we may say, might not have an operative mortality of greater than 5 or 10 per cent. Another operator might take a more radical stand, like that expressed by Bernays before our society eight years ago, viz., that practically all cancers should be extirpated regardless of the danger. Such an operator might in a series of cases get as high as 75 per cent. mortality, while a surgeon taking an intermediate view would save more lives and give more comfort than either, but would have a much larger percentage of deaths than the extremely timid surgeon who has 5 per cent. mortality. Therefore, it seems almost useless, not to say misleading, to report or review the statistics which have been given, and yet it is the only way by which we can form an approximate estimate of what we may expect. I will therefore quote some records of work done by the conservative class of surgeons who occupy a rational plane, although, as before stated, their statistics are no doubt based upon different premises. Hermann's statistics, according to Mayo, show that one-half of all cancers involve the alimentary tract and that one-sixth of the cancers of the alimentary tract are in the large bowel. Ewald's collection of over 1,100 cases gives their location as about nine in the rectum to two in the rest of the colon. Deaver, at the Cleveland meeting of the American Surgical Association in 1906, presented "A Year's Experience in Intestinal Surgery," and out of forty-six operations on forty patients for intestinal troubles, thirteen were cases of intestinal carcinoma, all in the large bowel. The cecum was diseased in four cases, the sigmoid in four, the hepatic flexure of the colon in two, the transverse colon in one, the splenic flexure of the colon in one, and the rectum in one. Five of these thirteen patients died—those in whom the splenic flexure and rectum were involved, one of those in whom the cecum was affected, and two of those in whom the sigmoid flexure was diseased. The remaining eight patients recovered from the immediate operation and were relieved temporarily, but of the four successful cases in which the patients were seen sufficiently early for radical operation to be done, two developed symptoms of recurrence about eight months later and were again temporarily relieved by further operation; and in the case of two others on whom a radical operation was done, sufficient time has not elapsed since the operation to permit of their being considered in this connection. Deaver says: "It is true of intestinal cancer, as of all other forms of malignant disease, that the surgeon seldom sees the patients early enough to offer them hope of radical cure. Early recognition of internal cancer is one of the desiderata of surgery. Among the thirteen patients herewith reported, only six were seen early enough to render any radical operation justifiable, and in most of these, during the past as during the former years, I have been forced to content myself with doing an entero anastomosis."

To get an idea of relative surgical success in various parts of large bowel we must resort to different authorities. Cumston and Vander Veer reported in detail, in Vol. XXXV, *Annals of Surgery,* the eighty-three cases of excision of the cecum for carcinoma recorded to that date. In ten of these reports it was not stated as to the immediate fatality. Of the other seventy-three, thirty died under the operation and forty-three recovered from the immediate operation. Most of these cases were performed by operators of international reputation. A very striking feature in the study of these cases is the great improvement in statistics from Bilroth down to the present. Willy Meyer, in the Cleveland Symposium before the American Surgical Association, reported his experience with operations on that portion of the large intestine which lies between the cecum and sigmoid, not including either. Inasmuch as Meyer has given briefly the details of his eleven cases, I will quote them here.

"Case I.—Female, 33 years old; cancer of hepatic curvature, with multiple metastases in ascending and transverse colon. Colocolostomy in July, 1888; uninterrupted recovery. Patient in excellent condition nine months later; had gained thirty-six pounds in weight; presented before the Surgical Section of the New York Academy of Medicine. The patient then left for Europe, so that further operating here, as intended, became impossible. Primary ileocolostomy and resection of the diseased portion of the gut at a second sitting, I now think, would have been more advisable in this case. As far as I have been able to determine from the literature, this was the first case of colocolostomy done for malignant stricture.

"Case II.—Male, 46 years: cancer of hepatic curvature, involving ascending and major part of transverse colon. Ileocolostomy, end-to-side, Murphy's round button, February, 1899, with excision at the same time. At first, satisfactory recovery; then, suddenly change for the worse, after severe attack of coughing; on changing dressing, ten days after operation, it was seen that wound had burst open again; peritonitis; death two days later. Layer sutures of catgut had been used for closing the wound. Since this experience I have always used through and through silk sutures for closing the abdomen in the male.

"Case III.—Male, 68 years; cancer of lineal curvature; intestinal obstruction; ileus. Ileosigmoidos-

tomy, October, 1902; death twenty-four hours later, from aspiration of fecal vomit and pneumonia. Primary enterostomy of caecostomy would probably have been the wiser procedure, but artificial opening was refused by family.

"Case IV.—Male, 46 years; cancer of transverse colon and hepatic curvature; very large tumor; fever; subacute peritonitis, due to perforation. Ileocolostomy; death six days later as a result of peritonitis.

"Case V.—Male, 65 years; cancer of ascending colon and hepatic curvature; intestinal obstruction for eight days; peritonitis, relief asked for but enterostomy refused. Therefore, exploratory incision; afferent part of intestine enormously enlarged; probably distention ulcerations, for gut bursts despite most careful handling; closure of rent; multiple incision of eventrated coils; Delenberg posture preceded as well as followed by stomach irrigation. At the moment that patient was lifted from stretcher into his bed, massive vomitus with aspiration occurred, causing instant death

"Case VI.—Female, 57 years; cancer of hepatic curvature, involving ascending colon. Ileocolostomy November, 1905. Excision of ascending and half transverse colon five weeks later; good recovery; patient well at the present time.

"Cases VII to XI.—All were cancer of upper part of sigmoid curvature, with symptoms of complete or partial intestinal obstruction; pronounced meteorism or symptoms of ileus. Treatment, small median or lateral exploratory incision on outer side of left rectus muscle, for the purpose of located suspected tumor, followed by typical oblique incision parallel to Poupart's ligament for colostomy (or later incision made at once, in order to avoid cuts): artificial anus in lower end of descending colon with spur formation. Three recoveries, two deaths."

Meyer then says that while the results in the foregoing cases are not particularly encouraging, it must be remembered that all, with the exception of case VI, were in a more or less hopeless condition when they came for treatment. In order to prove the results in a more favorable line of cases in which it is possible to do an immediate anastomosis, I wish to call attention to the sixteen cases of cancer of the colon reported by Jonas at the Boston meeting of the American Medical Association in 1906.

"Case I.—Primary endocarcinoma, located in sigmoid. Removed. Ends closed—lateral anastomosis. Needle and thread. Recurrence in five months.

"Case II.—Secondary to papillomatous ovarian tumor in the descending colon. Removed end-to-end. Czerny-Halstead suture. Free after one year. Lost from sight.

"Case III.—Primary. Adenocarcinoma. Located in upper end of descending colon. 1. Short circuit. Murphy button. 2. Growth removed, ileocolostomy. End-to-side. Recurrence in twelve months. Death in eighteen months.

"Case IV.—Primary. Adenocarcinoma (Ileocolostomy). Located in ileocecum. 1. Artificial anus from ileum. Lateral approx. Needle and thread. Well six months later. Not heard from since.

"Case V.—Primary. Adenocarcinoma. Located in ascending colon. Hepatic flexure. Excision, ends closed, lateral approx. Murphy button. Well two years later.

"Case VI.—Secondary. Cicatricial mass. Located in descending colon from uterus and tube. Removed end-to-end suture. Double supporting loop. Lost sight of after two months.

"Case VII.—Primary. Adenocarcinoma. Located in ileocecal region. Ileum planted into side of colon. Murphy button. Lost sight of four months later.

"Case VIII.—Primary. Neoplasm located in lower end of descending colon. Relieved by short circuit, with Murphy button. Died in three months.

"Case IX.—Primary. Adenocarcinoma. Located in lower end of descending colon. Removed end to end. Murphy button. Halstead suture, double row for support. Well after one year.

"Case X.—Secondary. Carcinoma. Located in appendix, head of colon, and ileocecal valve. Removed. Lateral approximation by suture. Moynihan clamps. Well six months later, then lost sight of.

"Case XI.—Primary. Carcinoma. Located in ileocecum. Removed end of ileum implanted to side of colon. Murphy button. Died.

"Case XII.—Primary. Adenocarcinoma. Located in splenic flexure. Removed end to end. Murphy button. Lembert reenforcing. Died.

"Case XIII.—Primary. Adenocarcinoma. Located in descending colon. Removed end to end. Murphy button. Lembert reenforcing. Well after one year.

"Case XIV.—Primary. Adenocarcinoma. Located in splenic flexure. Removed end to end suture. Czerny-Lembert. Double loop supporting ligature. Well after one year.

"Case XV.—Primary. Adenocarcinoma. Located in transverse and hepatic flexure. Closed ends. Lateral approximation. Murphy button. Died four months later from a fall producing basilar fracture. No return of growth.

"Case XVI.—Primary. Myofibrous polypus. Located in hepatic flexure. End to end. Connell-Cushing suture. Double loop suspension. Well after three years."

This report of Jonas' is most encouraging in that it shows us that cases operated upon while the patient is in good enough condition to withstand an immediate anastomosis and removal, the mortality should not be markedly greater than in other major intestinal surgery. Leaving the upper segments of the colon, we will take up the larger field which represents nine-elevenths of the cancers of the large intestine, viz., the sigmoid and rectum. Hartwell analyzes forty-six cases of cancer of the rectum, twenty-six in males and twenty in females. The greater numbers being from forty to sixty years of age. The mortality from operation was 26 per cent. Recurrence in less than two years occurred in 11 per cent., and there was a survival of more than three years in a similar percentage. Complete colostomy was found to be a satisfactory method of preventing sepsis and the operative mortality lowered by this method of operation. Tuttle's mortality for cancer of the rectum is 16 per cent. Kelsey's mortality has recently been as low as 3 per cent. in the lower segment of the rectum and 26 per cent. when it was necessary to open the peritoneal cavity. The Mayo brothers have during the past five years operated upon twenty-six patients for high rectal cancer by the combined abdominal and low methods, both surgeons working at the same time. Of these, seven died as the result of the operation or within the first month. Of the nineteen who recovered, two were not traced, but were known to be alive and well more than one year after the operation. Ten patients operated upon

too recently to be of value are alive and well now. One operated upon a year ago died before the end of the year. This is the only one of those operated upon more than a year ago, and who survived the operation, who failed to live one year. Seven lived over one year; five are alive now. Five lived over two years; three alive now. Three lived over three years, two alive now. As there were only four of those operated upon more than three years ago and two are alive and well, we have 50 per cent. alive and well over three years; too few from which to draw conclusions, but suggestive, says Mayo. The statistics of Tuttle, Hartwell, Kelsey, and the Mayos are sufficiently alike to be suggestive of the mortality of operative treatment of cancer of the rectum.

I wish here to give a report of personal cases operated on during the past year from June 5, 1906, to June 6, 1907.

Case I.—A woman, aged 32, referred to me by Dr. Osmond Royal, of Portland, to whom the case had been referred by another physician as one of appendicitis. Gave history of several months gradually increasing constipation, until finally obstruction became complete. The pain in the right side had gradually increased and at this time was very severe, inasmuch as the location was right for appendicitis, it might readily be diagnosed as appendicitis. The glands around the cecum and ileocecal valve were enlarged. The patient was much emaciated and showed a decided cachexia. The patient was young and we decided to do a radical operation by removing all the glands and mesentery in this neighborhood along with a good portion of the ascending colon, ileum, cecum, and appendix. (See Fig. 1.) An anastomosis was made between the ileum and that portion of the ascending colon which was left near the hepatic flexure. The patient made an uninterrupted recovery, soon regained her normal health and has remained in perfect health up to this date. (Jan. 23, 1908.)

Case II.—A man 52 years old. Patient had been treated by home remedies for several days after showing signs of intestinal obstruction. The patient was referred to a colleague who immediately recognized intestinal obstruction, but was not positive as to the nature of the obstruction. He therefore waited a day or two. Finally the resident physician noticed a tumor protruding through the rectum which proved to be a cancer of the sigmoid which had been forced out through the anus. It was at this time that I was called in consultation by Dr. Locke. The patient had had no action of the bowels for thirteen days and had not even passed gas. He had been vomiting fecal matter for several days. Consequently, he was in a state of profound shock. Cold, clammy perspiration stood out on his face and body. Surgical means were urgently indicated. We therefore opened the abdomen as soon as possible, and with an assistant pushing up the tumor through the rectum from below, the intussusception, which had formed, was reduced. We thought at the time of doing a temporary operation, but the nature of the case and the wishes of the patient's friends compelled us to decide on radical operation. We therefore excised the growth (see Fig. 1) and made a lateral anastomosis with clamps. Approximately, a gallon of foul, dark liquid fecal matter passed through the newly-made opening and out through the anus, involuntarily. The patient stood the operation well, considering his condition, but died two days later of stercoremia and peritonitis. This patient might possibly have been saved by a two-stage operation, but I do not think it probable.

Case III.—A woman, aged 32, a trained nurse, referred to me by Dr. E. A. Pierce for whom she was working. A year before she had consulted a prominent internist in one of the Eastern centers, who pronounced her case neurasthenia and constipation of a hysterical type. He did not benefit her, so she went to a surgeon who removed her appendix but failed to find the obstruction. She lost flesh and gradually grew worse until she would take severe cathartics for several consecutive days before producing results. Her pain seemed to be located in the region where the appendix had been removed. The thought of adhesions in this neighborhood was given due consideration. I was called to see the case two weeks before the operation was done. The patient had lost flesh, had a yellow color, and obstinate constipation with every evidence of some kind of obstruction. As a test, I ordered aloes, strychnine, and belladonna pills, and later ordered considerable doses of castor oil without producing results or without causing great discomfort. During these two weeks I did not see her, but practically no action of the bowel was obtained. Extensive sores had formed in the mouth as the result of stercoremia and digestive disturbance. At this stage I had her come to my office where I made an examination which I had foolishly refrained from doing at first on account of her modesty, and discovered

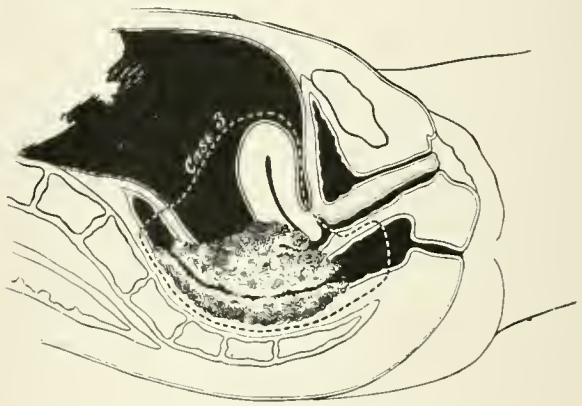

Fig. 2.—Tumor and extent of operation in Case III.

the rectal and vaginal growth shown in Fig. 2. I told her her condition and she insisted upon a radical operation and not a colostomy. An abdominal incision was made, when it was found that the growth involved the uterus and rectum to an extensive degree. The internal iliacs were ligated as a preliminary step. The mesorectum was severed just below the brim of the pelvis. The pelvic and abdominal wounds were then packed thoroughly with gauze to protect the peritoneum temporarily from infection while I worked below. I then split the perineum and rectovaginal septum as advised by Murphy. The sphincter ani was left and the mucous membrane covering it, as I hoped to do a combination of the Murphy and Weir operations. The cancer was then removed, including the rectum almost to the promontory of the sacrum. The uterus, tubes, and all fat and glands in the hollow of the sacrum were also removed. The sigmoid was brought out, but was found to be too short to reach the rectal segment. Consequently, it was partially attached to the vaginal mucous membrane. After changing gloves, I returned to the abdominal wound and carefully sutured the pelvic peritoneum, forming the broad ligament around the newly placed intestine, thus walling that wound entirely from the peritoneal cavity. No evidence of peritonitis or

sepsis developed, but the sores in the mouth grew larger under all forms of treatment, until it became impossible for the patient to take nourishment, and she died of starvation four weeks after operation. Post mortem showed perfect walling of wound and no sepsis at open wound.

Fig. 3.—Showing the extent of operation in Case VI

Case IV.—Woman, aged 64 years, referred to me by Dr. Jos. R. Numbers, of Weiser, Idaho. This patient gave a history of gradually increasing constipation covering a period of more than a year. She had had evidences of almost total obstruction for about four weeks, when she came to me, and was vomiting all fluid taken and in addition the contents of the bowel. A vaginal examination showed that the tumor was well fixed and occupied the large intestine as it passed over the promontory of the sacrum. On opening the abdomen it was found that the growth was so firmly fixed that it would be impossible and useless to remove it. We did a left inguinal colostomy (see Fig. 1), bringing down the intestine from as high up as possible and out through a gridiron incision. The surprising feature of this, as is often found, was that the bowels acted regularly once a day, and the patient was up on time and went home in a very comfortable state, and at last reports was still very comfortable. Kelsey claims to have seen patients that lived for five years after a colostomy in comparative comfort.*

Case V.—Woman, 43 years old. This was the most extensive and most thoroughly inoperable case of the series. As it will be seen, it included the

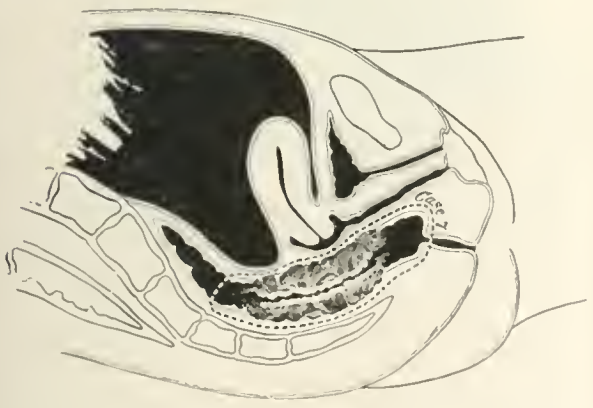

Fig. 4.—Tumor and portion of bowel removed in Case VII.

hepatic flexure, half of the transverse colon, and part of the ascending colon. The obstruction had been complete for four weeks and vomiting had continued during this time. The patient had put off operation until the last moment, and as she was too weak to move, I was called to Grant's Pass (three hundred miles away) by Dr. Loughridge to operate. She was very positive in her demands for a radical operation, even though death resulted, and was very much opposed to an artificial anus. Therefore, we were prepared to take long chances. We found that the ileocecal valve acted perfectly so that gas could not return through it. The consequence was that the cecum was distended to an enormous size. We removed the cecum, portion of the ileum and the colon almost to the splenic flexure, as indicated by the dotted line in Fig. 1. The condition of the peritoneum covering the small as well as the large intestine, was such as to make inadvisable an anastomosis at this time, so the end of the ileum was drawn out through a special opening in the right groin. The patient made very rapid improvement and one month later I went to Grant's Pass and did an ileosigmoidostomy, closing the ileum which had led to the surface. The patient recovered well from the operation, but the growth returned along the posterior abdominal wall, and the patient died three months after the first operation from general cancerous condition.

Case VI.—Referred to me by Dr. Locke, who assisted with the operation. The patient was a lady

Fig. 5.—Site of stricture and portion of bowel removed in Case VIII

about sixty-four years of age. As is seen in the illustration, the cancer developed just inside the sphincter, a small portion of it showing through the external sphincter on the front surface. The vaginal mucous membrane was split after Murphy's method, the entire rectum and anus, including the sphincter muscles, wre dissected out, as shown by the dotted line (Fig. 3), including all fat and glands in the hollow of the sacrum. The upper rectum and sigmoid flexure were dissected up and brought down through the opening and the perineum sutured. The patient made an uninterrupted recovery and was, when last heard from, in very good health. The sigmoid served its function as a container admirably in this case, the bowels acting but once a day as a rule. There was very little soiling of the pads.*

Case VII.—A woman, aged 36 years, was referred to me by Dr. Esther Pohl. She gave a history of having had, as she said, a large ulcer removed just five years before. At this time the rectum was entirely closed except for very thin liquids. There was about two inches between the internal sphincter and the lower growth, so we split the perineum according to Murphy's method, and dissected out the rectum up nearly to the promontory

*This patient died eight months after the operation, but had been greatly relieved during her life.

*January 23, 1908, one year and two months after operation, no recurrence and patient in good health.

of the sacrum (Fig. 4), opening the peritoneal cavity, and drawing the sigmoid down through the original anus (for in this case we left the sphincter) and sutured the intestine to the margins of the skin around the anus. We used drainage back of the rectum in the ischiorectal fossa. The patient did

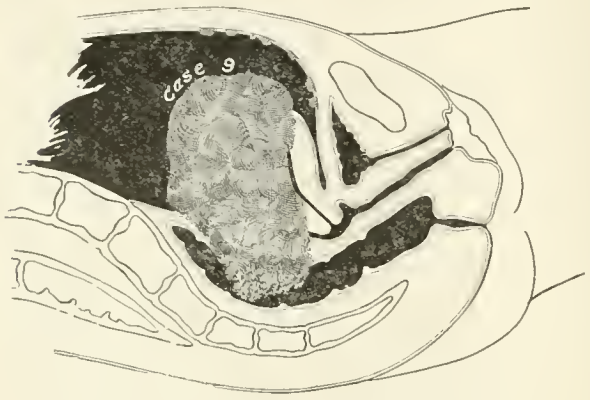

Fig. 6.—Showing the inoperable tumor in Case IX.

well for five days, having no unfavorable symptoms, when she died very suddenly of pulmonary embolism. This case was looked upon as one of the most favorable I had had, from the standpoint of making a cure, had it not been for this complication.

Case VIII.—A woman, aged 44 years, was referred to me by Dr. Gustav Baar. As will be noticed by the drawing (Fig. 5), the stricture was about two inches above the sphincter muscle. She gave a history of more or less obstruction at this point extending over a period of fifteen years, but recently the growth had taken on an active increase and looked very much like malignancy. The obstruction at the time she presented for operation was complete for everything except very thin liquid. The rectum was removed by Murphy's method, the upper segments brought down and sutured to the mucous membrane of the anus. The perineum closed and drainage placed in the ischeorectal fossa. The results were all that could be desired and sphincteric action was quite satisfactory.*

Case IX.—A woman, aged 46 years, twenty years ago had an attack of peritonitis, possibly the result of a miscarriage. Three years ago she suffered from neurasthenic indigestion without pelvic symptoms. Because of her nervous state, Dr. Mae Cardwell examined the uterus, which was apparently normal, but retroflexed and prolapsed and irreducible. She then did not see her until two weeks prior to the operation. Two years prior to the operation, the patient had a severe attack of pain in the stomach resembling indigestion which was treated by another doctor. Constipation had not been a marked symptom. Just before she was seen by Dr. Cardwell the last time, she consulted a doctor for pain in her stomach with symptoms of pressure on bladder and rectum. During this month mucus, tinged with blood, passed at various times from the rectum. Three days before the operation was performed, which was exploratory, Dr. Cardwell gave her three grains of calomel which was followed by a marked hemorrhage from the bowel. No hemorrhage had occurred from the uterus at any time, and no erosion of the cervix existed. An exploratory laparotomy revealed the condition existing. I may here state that while the growth seemed to appear in the rectum, producing hemorrhage, it was thought probable that it was simply a fibroid which had by pressure forced its way through the rectum. Therefore an exploratory operation was thought justifiable. On opening the abdomen, the growth was found to be unquestionably malignant, the tumor itself, which involved a large portion of the uterus and filled the pelvis entirely (see Fig. 6), extended far out into both broad ligaments, and also involved the neighboring peritoneum as shown by the small nodules in front of the uterus. The case was clearly inoperable except by ligating both internal iliac arteries. Inasmuch as the peritoneum and all neighboring tissues were involved, it was seen that such an operation could do no permanent good. The abdomen was then closed and the patient necessarily left to her fate, which must be death. There is no obstruction, therefore an operation of colostomy or curetting of the rectum would do no good at the present time. It might be of value later.*

Case X.—This patient was referred to me by Dr. Rogge, June 6, 1907. The first symptoms were that of hemorrhage. Cachexia was very marked and the patient was rapidly losing flesh and the tumor was large without causing any marked obstruction (see Fig. 7), consequently she was advised not to have an operation performed.†

Case XI.—This was not a cancer case, but is given as an illustration of the removal of the entire colon except the rectum (see Fig. 8), with perfect results as far as function was concerned, redemonstrating the fact that if it is necessary in cases of cancer, the entire colon can be removed without seriously damaging the health of the patient, as has been demonstrated by Mayo and others.

Thus during the year, I have been called upon to treat ten cases of cancer of the large bowel, all but two of which have been of the far advanced type in some one of the three forms of far advanced cancer. Of these patients, eight were operated upon. Two of them died within six days of the operation, one as a result of the stercoremia existing, and the other as a result of pulmonary embolism, which might occur in any surgical operation and is to be classed under the heading of surgical

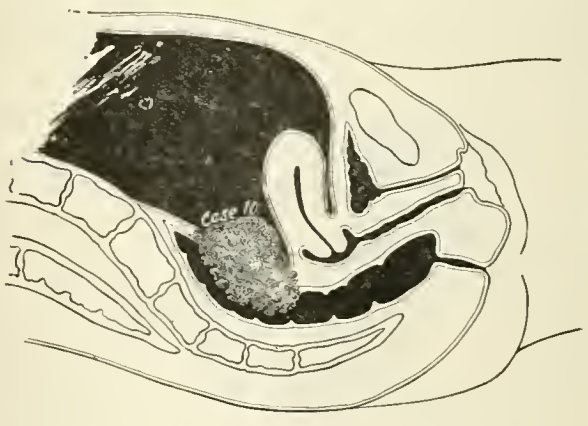

Fig. 7.—Showing the tumor (not removed) in Case X.

contingencies. One patient died of starvation, after four weeks, due to large areas of ulceration involving the mouth and esophagus, thus preventing

*The result is still good now, eight months after operation. Unfortunately the specimen was not examined and was misplaced, so we are not sure it was malignant.

*December 22, 1907, seven months after exploration, was called to do a right inguinal colostomy, as complete obstruction with vomiting had existed twenty-seven days. January 28, 1908, patient much more comfortable and is taking nourishment very well.

†Died about November 6, 1907, without obstruction becoming complete.

the patient from swallowing. This case, if it could have been diagnosed and operated upon six weeks before, would unquestionably have been a successful case for some months if not permanent. Case V. was too far advanced to hope for permanent cure, but by doing the operation in two stages, the patient recovered from the operation and lived three months after the first operation, dying from a direct toxemia of the cancer, instead of drowning in fecal matter. Case III ended fatally as the result of starvation. The life of the patient in Case III, while it was not shortened by the operation, was evidently not appreciably lengthened. In Case IV the patient was made more comfortable. In Case V life was prolonged probably two and one-half months and made more comfortable. Cases I, VI, and VIII are cases which promise to be cures. Case VII was one of the most promising cases, had it not been for the surgical accident. Case II would probably have been cured had the patient been operated on early. Cases IX and X were advised to have no radical operation performed, inasmuch as the disease is evidently beyond hope of cure and as there is no obstruction.

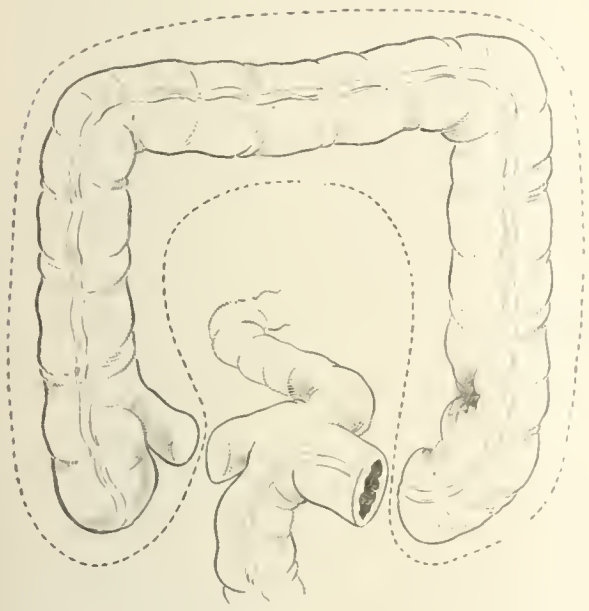

FIG. 8.—Complete excision of colon one year after ileosigmoidestomy performed for cure of ulcer of descending colon in Case XI.

As we have three grades or degrees of far advanced cancers, so we have three methods of treatment for far advanced cancer. Witzel puts it very nicely in a short rule as follows: "Small cancers, large operations, large cancers, small operations." The fact remains that almost all cases of cancer of the colon are best treated by some form of surgical operation, and if by any means we can make it easier to make diagnosis early, we will certainly greatly modify the death rate of this frightful disease.

I have not gone into the methods of diagnosis, as these you will find in your text books. I may simply state that they all fail frequently in the hands of the very best doctors. Therefore the only safe plan in cases of bowel trouble in which the symptoms are marked and withstand all forms of treatment, if accompanied by emaciation out of proportion to the other symptoms, is to advise an exploratory incision which is almost devoid of danger under proper conditions (in case there is no growth) and will allow of a diagnosis of many cases of cancer early enough to produce a radical cure while otherwise the diagnosis would necessarily be postponed until treatment would fail. I have reported the cases here for the purpose of adding to the literature of the subject. There is no part of the large intestine which is beyond the reach of surgical methods, even in the presence of far advanced cancer, for even in this small series, as is shown by the pictures, I have been called upon to remove every single section of the large intestine from the ileocecal valve to the anus, in one year's experience. If a diagnosis can be made early enough, we can certainly produce a remarkable showing in the treatment of cancer of the large bowel, for if we can get such results in cases so far advanced, what can we not do with earlier diagnosis? Then the principal point I would emphasize in answering this question is: first, and above everything, let us study to make earlier diagnosis, and if the family physician suspects the development of cancer and cannot determine positively, it is well for him to call a surgeon in consultation. If they cannot reach a conclusion, let them agree on the one point of an exploratory incision. Those cases which have been allowed to become far advanced cancers, we may treat by some of the methods described, each case being a law unto itself.

Far advanced obstructive cancer, not pathologically extensive, should always be excised. For extensive growths producing obstruction, excision may be used in certain cases with hope of relief, if not cure, but a larger percentage are best treated by some form of entero- or colocolostomy or colostomy.

Extensive growths with marked cachexia and producing no obstruction, should be treated by meeting the medications with curetting, late colostomy, etc. In answer to those who say, "let these far advanced cases die and get out of their misery," I would say that the profession is not ripe for euthanasia yet and I understand our duty to be: (1) Use desperate and radical means to remove cancers in all cases where there is a reasonable hope of cure either temporary or permanent. (2) In irremovable cases, perform such operations as will prolong life or add to the comfort of the patient.

SANITATION OF THE CANAL ZONE.*

By COLONEL WILLIAM C. GORGAS, M.D.,

ASSISTANT SURGEON-GENERAL, U.S.A.; CHIEF SANITARY OFFICER, ISTHMIAN CANAL ZONE DEPARTMENT OF HEALTH

A SHORT historical résumé of the work for the prevention of yellow fever and malarial fever, based upon the knowledge that the mosquito is the only means of conveying these diseases from man to man, may be of interest, before passing directly to the work at Panama.

The first real knowledge we had that the mosquito was a conveyor of disease was Manson's discovery that certain species of mosquitos, principally *Culex*, conveyed from man to man *Filaria sanguinis hominis*. Manson made this discovery about 1880. A considerable time after this, about 1896, an English military surgeon, Ronald Ross, discovered that malaria was transmitted from man to man by the *Anopheles*. This discovery was vastly more important, and made a much more universal impression, than Manson's discovery.

Filariasis is almost exclusively a tropical disease and does not cause man a great deal of trouble, unless it produces elephantiasis, and elephantiasis is only an occasional result of filariasis. Elephantiasis

*An address delivered before the New York Academy of Medicine at the anniversary meeting, November 29, 1907.

bears about the same relation to filariasis that phlebitis does to typhoid fever, occurring in about the same ratio. Malaria is a world-wide disease prevailing in the temperate zone as well as in the tropics, and, therefore anything tending toward its prophylaxis was much more important than the discovery concerning the prophylaxis of filariasis.

Some years after Ronald Ross's discovery with regard to malaria our Army Board, consisting of Reed, Lazear, Carroll and Agramonte, made a similar discovery with regard to yellow fever. The discovery with regard to yellow fever was as important to the western hemisphere as was the discovery with regard to malaria to the world. All of these discoveries were more or less assisted and led up to by the work of other men in this same field. Laveran, a French naval surgeon, about fifteen years before Ross's discovery, had proven that a certain plasmodium was the cause of malaria, and the work of Reed's board was assisted a great deal by Finlay's and Carter's work in the field of yellow fever. But Manson, Ross, and Reed stand out preeminently as the men who made the discoveries that have enabled us to do such successful work with regard to the prophylaxis of yellow fever and malaria.

No practical application was made of this knowledge until the year 1901, when the Sanitary Department at Havana, then under the military control of our government, devised and put into execution methods based upon the idea that the *Stegomyia* mosquito was the only means of transmitting yellow fever. These methods at Havana were equally efficacious against malaria, and since that time they have been successfully applied many times against both malaria and yellow fever, and are now universally accepted as the proper prophylactic measures for preventing these two diseases.

When the Spanish-American war broke out the question of protection from yellow fever was of much more importance to the United States than the question of the prophylaxis of malaria. A large part of the United States, every few years during the preceding century, had been ravaged by this disease, and the quarantines which were established between the various localities completely paralyzed business in the affected areas. This caused people living in the affected communities to consider it a very dreadful disease.

A large proportion of the epidemics in the United States had been started by importations from Havana, Cuba, and when Cuba was occupied by the military forces of the United States every energy was bent toward ridding Havana of yellow fever. It was considered at that time that if there was any one disease due to filth and uncleanliness, yellow fever was preeminently that disease; so the military authorities in Havana bent every energy toward cleaning up and putting the city in what was at that time considered first-class sanitary condition. In this they were successful. The streets of no city anywhere could have been kept cleaner than were the streets of Havana during the year 1900, under the supervision of Colonel Black of the United States Army. And other sanitary measures, then believed to be important, were put in force with equal care by the Sanitary Department. Yet the cleaner and in the better sanitary condition we got the city, the worse yellow fever seemed to get, and the very part of the city that we kept in best shape had yellow fever the most extensively.

During the latter part of 1900 Reed's Army Board was sent down by the Medical Department of the army to try to discover some reason for this condition of affairs. You are, no doubt, most of you familiar with the details of the work of this board. It was a very dramatic and, it seems to me, the most mathematical piece of work ever done in medicine, either before or since that time. They took men, put them out in tents in the country, and kept them there under guard for a period of two weeks. As the incubation period of yellow fever was known to be six days, if they remained there free from fever for two weeks it was proof that they had not contracted fever before going there. They would then take mosquitos, which had before bitten yellow fever patients, and have them bite these men, and within from three to six days the men developed yellow fever. There were quite a number of cases of this kind. This proved positively that those men contracted yellow fever from these mosquitos and in no other way.

To make it still more impressive, Reed built a small house, so screened that mosquitos could not get in, and divided this house into two rooms by a wire screen, so that the mosquitos could not pass from one room to the other. He then put a man in each of these two rooms. In one of the rooms he liberated a few infected mosquitos, and the man who lived in the room developed yellow fever after three or four days; the other man, although all conditions were exactly the same, with the exception of the mosquitos, continued to live in good health.

He then built another house close and tight, with no ventilation whatever. In this room he placed the mattresses and sheets and clothing of patients who had died of yellow fever. Two men were kept in this building every night for a considerable length of time, yet none from this exposure contracted yellow fever. It had been universally accepted that yellow fever was ordinarily conveyed by clothing, baggage, and fomites of people who had yellow fever, or from localities where yellow fever prevailed.

In about February, 1901, the Sanitary Department put into operation methods based upon the ideas advanced by Reed's board, and in September, 1901, the last case of yellow fever occurred in Havana. It must be remembered that yellow fever had prevailed steadily and extensively in Havana for the preceding one hundred years without the break of a year or a month. Havana remained entirely free from yellow fever for five years.

The methods devised for the extermination of yellow fever were necessarily directed against the destruction of all mosquitos, and were, therefore, equally successful against malaria. Considering the character of the disease, the disappearance of malaria from Havana was about as complete as that of yellow fever. Within the last eighteen months yellow fever has reappeared in Cuba to a slight extent, but this reappearance is considered as being due rather to laxity in the methods used than to any fault in the principle that the *Stegomyia* mosquito is the only conveyor of the disease. The sanitary work in Cuba was turned over to the Cuban Government in 1902. About the time of the reappearance of yellow fever in Cuba an extensive civil war was brewing, which naturally paralyzed the efforts of the Health Department of the island.

The success of the mosquito work in Havana was so marked and prompt that it attracted universal attention, and since that time there have been many examples in all parts of the world of successful work against both malaria and yellow fever accomplished by the adoption of the methods worked out at Ha-

vana. One of the most striking and important of these examples is that recently accomplished at the Isthmus of Panama, where, as you know, the United States is constructing an interoceanic ship canal. The Isthmus of Panama runs in a general direction east and west, and comes to its narrowest point about the center of the Republic of Panama. The lowest point in the mountain range extending from northern North America to the southern point of South America is located where the canal crosses. The isthmus is probably narrower about thirty miles east of the present location of the canal, but the mountain range is so much higher at this point that it would involve a more expensive route. The route, therefore, for the canal was selected between Limon Bay on the north and Panama Bay on the south. This had been the route of greatest travel for crossing from the Atlantic to the Pacific ever since the discovery of America.

This particular locality had acquired the reputation of being an exceedingly unhealthful locality, and that reputation still clings to it. My attention was recently called to the fact that the general instructions to pilots of the English merchant marine state, under "Climate": "The Panama Canal district is one of the hottest, wettest, and most feverish regions in existence. Intermittent and malignant fevers are prevalent, and there is an epidemic of yellow fever at times. The death rate under normal conditions is large," etc.

I must confess that as far as past evidence goes this reputation is rightly deserved, but I do not believe the Isthmus of Panama is more unhealthy than any other tropical country where the rainfall is heavy. Wherever there is plenty of fresh water with a warm, even temperature mosquitos will readily breed all the year round. Now, if into this locality you introduce the white race and the infection, you will have yellow fever and the malignant forms of malarial fever.

From the location of Panama it happens that these conditions have existed more or less continuously for the past four hundred years. There were always some unacclimated whites crossing the isthmus at this point who contracted this disease, and several times in its history there have been very large numbers brought together here. In no other place in the tropics have these conditions existed so continuously and to such an extent. For this reason the unsavory reputation of Panama has spread over the world.

For three hundred and fifty years the isthmus was used only by Spanish soldiers, officials, and merchants going to the west coast of North and South America. These suffered heavily from diseases, malaria and yellow fever, contracted on the isthmus. In 1849 the isthmus was a favorite means of transit for American miners going to California. They suffered heavily from the same cause. From 1850 to 1855 there was a considerable force at work building the railroad from Aspinwall to Panama. Malaria and yellow fever affecting the constructing force was one of the greatest obstacles met in the building of this railroad. Then the French from 1880 to 1889 had a very large force here constructing the canal. Their losses were about as severe from yellow fever and malaria as anything that has occurred in the history of the tropics, and the health condition was looked upon as being the greatest single factor causing the failure of the French company.

When the United States, in 1904, undertook the construction of the Panama Canal they resolved to profit by the experience of their predecessors on the isthmus for the preceding four hundred years, and also to profit by the knowledge that had been recently acquired with regard to the prevention of malaria and yellow fever. The line of the canal extends from Colon on the north to Panama on the south, in a slightly southeasterly direction, Panama being to the east of Colon. The plan adopted by the United States for getting ships across the isthmus is really the formation of two large lakes. The Chagres is to be dammed near its mouth on the north side, and the Rio Grande near its mouth on the south side. These dams will back the water up to the dividing ridge, the two lakes being about seven miles apart. Through this seven miles of hills we are digging the canal that will connect the two lakes so that ships can pass through one to the other. To get into the lake ships will have to be raised by three locks eighty-five feet; they will then sail south through the lake on the Colon side, through the canal connecting the northern with the southern lake, through the southern lake, and then descend through locks into the Pacific.

The Panama Railroad, finished in 1855, and operated continuously since, runs along about the center of the work from Colon to Panama, Colon being the northern terminus of the road. Between Colon and Panama along the line of the railroad are at present some seventeen towns, with populations ranging from one thousand to three thousand, besides some forty villages for laborers. By treaty the United States controls a strip of territory ten miles wide extending from Colon to Panama. The cities of Colon and Panama are exempt from the jurisdiction of the United States, except with regard to sanitation.

When the United States took charge yellow fever prevailed in Panama and Colon, and in the villages between these points, not to any great extent, but enough to indicate that the infection was there. Malaria was universal. The sanitation of the isthmus really revolved about measures for the repression of yellow fever and malaria. We knew that as the force was increased these diseases would increase and become more prevalent, as they had on all former occasions when the force increased. We therefore resolved to adopt the same measures that had proved effective in Havana, modified as the necessity for applying them varied under the conditions existing at the isthmus. The Sanitary Department had many functions that had very little bearing upon health, but were assigned to us because it was thought necessary to do them, and they came nearer to the duties of our department than to the work of the Engineering Department or to the other organized divisions.

Our attention at first was turned principally toward getting rid of yellow fever, and this work centered mainly about the towns of Colon and Panama. With this in view we adopted the same measures which had been worked out at Panama, but, unfortunately, we were not able to put them into execution until February, 1905, at which time we had been in control of the isthmus some ten months. This was due to the fact that the commission was unable to furnish the necessary supplies, and to the further fact that the legal adviser of the commission thought we could not legally make expenditures in Colon and Panama. In February, 1905, these difficulties were finally surmounted and work was commenced along the indicated lines.

By this time a considerable number of nonimmune whites had come to the isthmus in the employ of the commission, and yellow fever began to affect

the force very generally. In April, 1905, two of the highest officials on the isthmus died of yellow fever, and this caused a widespread panic and a pretty general stampede. Many of the employees precipitately resigned and left. Our people very generally looked upon the mosquito theory as a failure. The natives laughed at us. And the executive board of the commission itself, as late as June, 1905, stated that the sanitary work of the isthmus had been a failure, and recommended that the personnel be changed and other methods tried. But the supreme authorities, who were aware of the handicaps and difficulties by which the Sanitary Department had been beset, gave us steady support, and by the following December yellow fever had disappeared from the isthmus. These were practically the same results as obtained in Havana, and in about the same time.

The malarial problem was quite different from that at Havana. The *Anopheles,* as a rule, is a country mosquito, and breeds only in clear, fresh water containing grass and algæ. It is therefore only in the suburbs of a city that many anopheles breed. The bulk of our force at Panama is scattered for forty miles along the railroad, in a country district, where all the conditions are favorable for malaria.

The plan adopted was to put measures into effect which would prevent the breeding of mosquitos in the neighborhood of the fifty odd villages and camps scattered along the line of the railroad. The anopheles mosquito is not much of a flyer, a hundred yards probably being the limit of its flight. It was therefore believed that if the breeding places could be destroyed within a couple of hundred yards around every village malaria would be controlled. It was not thought necessary to make any effort toward controlling the breeding of mosquitos in the large area of swamp land away from camps and villages. The expense of such measures would be very large, and probably not necessary for the accomplishment of our purpose.

The line of the canal was divided up into a number of divisions, each division placed in charge of a sanitary inspector, and laborers put to work ditching and draining, and oiling where drainage measures could not be carried out. This has been going on for the past three years. We have at present about a thousand men engaged in this work.

The work has been more successful than the most sanguine among us, in the beginning, hoped for. The sick rate during the last fiscal year was twenty-nine per thousand for a force of thirty-two thousand (32,000) men. As this is as low as the sick rate for a similar body of men working in the United States would be, I think we can claim fairly that malaria is under control. The death rate among the five thousand Americans for the same period was 6.4 per thousand from disease. This is about as small a rate as the same number of men would have in New York City.

We still, of course, have malaria on the isthmus, and, therefore, have not been as entirely successful with malaria as we have been with yellow fever. Yellow fever has long been gotten rid of in New York and Philadelphia, but malaria is still not uncommon in the country districts about those cities. The difficulties are inherent in the disease itself. The malarial mosquito breeds much more universally in country districts than does the yellow fever mosquito. A man when he contracts yellow fever will infect a mosquito for only three days, whereas when he contracts malaria he may be able to infect mosquitos for three years.

There has been some criticism to the effect that while our work has been successful, it has been unduly expensive. And there has been some ground for this criticism, when the sums of money expended, only, are taken into account, without considering the work accomplished by this expenditure. Our expenses during the past fiscal year were about $2,000,000, and will be the same in the present fiscal year. It would appear very large if it were announced that the Health Department of New York cost $2,000,000. It would be excessive, and it would be still more excessive on the isthmus, if the Sanitary Department performed only the same functions that the Health Department of New York City does. The Sanitary Department of the isthmus really performs the whole work that the government of the city of New York does, with the exception of the work done by the judiciary and police. The expenditures we make in the field covered by the Health Department of New York City would not cost us more than $30,000 per year out of the $2,000,000.

The Sanitary Department at Panama does the quarantine work at both ends of the isthmus, cares for the sick among the laborers and among the civil population, cares for the insane, the lepers, and the destitute, and in addition pays the expenses of the church.

The commission, in order to encourage the development of church work on the isthmus, appointed some dozen or more chaplains to the different hospitals. These chaplains were encouraged to do work outside of the hospitals, and have gradually built up congregations everywhere along the zone. The Sanitary Department pays the salaries of these chaplains.

Of this $2,000,000 I am sure $500,000 would amply cover the expenditures that bear directly upon the health of the employees; that is, I think that by the expenditure of $500,000 directed solely to sanitary work the present health conditions could be kept up. I do not mean to say I would advise that such a step be taken. The other million and a half of the appropriation is just as necessary, but not for sanitary reasons.

For instance, we spent last year $1,000,000 in the care of our sick. But the care of the sick has little sanitary bearing. It has to be done by somebody in every civilized community, and the Sanitary Department at Panama is the organization best fitted for this work. I wish to emphasize the fact that the words "Sanitary Department" do not at all convey an idea of what our functions really are at Panama.

I think, then, that the Sanitary Department at Panama can justly claim that it has accomplished what it was ordered to endeavor to accomplish. Its members were sent to the isthmus to establish, if possible, such measures as would protect the health of the laborers on the isthmus, so that the canal might be built. Former work on the isthmus had demonstrated the fact that the undertaking could not possibly be finished unless health conditions were ameliorated.

At the end of three years' work the sick rate of laborers on the isthmus is less than that of similar bodies of men at home. The death rate of our American employees is as small as it would be if they were living in New York City. Yellow fever has now practically been absent from the isthmus for two years and malaria is also entirely under control.

A METHOD OF MILK PRODUCTION.

By CHARLES L. [illegible], M.D.,

NEW YORK.

My object in writing this paper is to suggest a practical method by which I am convinced that a large quantity of milk in its natural raw state, obtained from healthy tuberculin tested cows and having a very low bacteria count, can be produced and marketed at a price that will place it within reach of the masses in the city.* The method is not a theory, but is one that has been tested under actual working conditions and that can be put into operation with only slight readjustment of business conditions in the milk industry.

Eight years ago I became possessed with the idea that if I, a physician, went into the business of producing clean milk, other things being equal, my professional training would attract to the enterprise not only the capital necessary, but also the support of the public. But there was a factor even more necessary to commercial success that I had overlooked, and that others who have gone into the same business with an enthusiasm equal to mine have overlooked. It was this—that the milk industry is of a most complex character and one which requires more study and preliminary training to bring commercial success than many of the other great industries. My education of four years on the producers' end of the business was both difficult and costly. By that very fact, however, the lessons in milk sanitation and milk commerce were the more thoroughly taught. These lessons have been emphasized since and form the basis for the suggestions contained here. For this reason, and because they will lead by natural steps to the method of milk production I have to propose, I will briefly outline the series of experiences.

All of the things required by the Certified Milk Commissions on their dairy farms I had in my possession when I began the production of clean milk in the year 1901. I had even more than these, for the plant was a model at that time and attracted wide attention. The care exercised in every detail of the dairy processes resulted in a milk with an extremely low bacteria count, as is attested by the records of the Milk Commission which certified to the excellence of the milk at that time.

But the demand for our milk soon reached a point far beyond the capacity of my new sanitary stable of fifty cows to supply. The operating expenses also made it imperative that the income of the establishment be increased. Unfortunately, I had not the capital necessary for the construction of new stables. In this extremity I decided to experiment with an old barn located on the place at some distance from the dairy house. The walls and ceiling of the structure were covered with strong tar paper and given a coat of whitewash. A platform and drop were constructed of tongued and grooved boards for the cows to stand upon. Twenty cows were then installed in this make-shift stable. The two men who did the milking received sterile milk cans and pails at the dairy house, carried them to the old barn in a wheelbarrow, and returned with the milk in the same way to the dairy house, where it was bottled and cooled.

In my laboratory on the premises samples of all milk produced were analyzed daily for the number of bacteria present. The bottles containing samples were placed under exactly the same conditions as milk sent to market, and analyses made at the end of twelve and twenty-four hours. The bacteria counts represent not the condition of freshly drawn milk, but of milk as it reached the consumer. Appended I present the tables showing the comparative counts of milk from the sanitary stable and from the improvised cow barn, the daily counts being averaged for each month for one year. The routine method of analyses was followed, *i.e.* 1 c.c. of milk was plated in nutrient agar and the

*Statistics of the New York City Milk Supply.—From various sources we learn the milk supply of Greater New York is 1,800,000 quarts daily. The average milk production per cow in New York State is six quarts daily (U. S. Government report). There are about 300,000 cows distributing milk to this city. Each cow is worth about $40, and this represents $12,000,000 invested in dairy cattle. Under present methods the land necessary to support a cow is about four acres, making 1,200,000 acres, worth an average of $40 per acre, the total of $48,000,000 invested in land. The equipment on the farm costs $100 per cow; therefore, about $30,000,000 is invested in this branch of the industry. For the dealers' share in the business there is invested for creameries, bottling establishments, pasteurizing plants, stables, horses, wagons, and the like a sum estimated at $18,000,000. Connected with the business there are at least 50,000 men employed in the country districts and 10,000 at work in town.

The milk sold in the city is of several kinds and may be classified as follows:

Raw milk.....	1,200,000	quarts daily
Pasteurized milk.....	600,000	" "
Certified milk.....	16,800	" "
Inspected milk.....	5,000	" "

Thus it appears that raw and pasteurized milk form 99 per cent. of the supply. Dairy farmers in seven States—New York, New Jersey, Pennsylvania, Connecticut, Massachusetts, Vermont, and Ohio—send in milk. Some milk trains are twenty-four hours on the road. The farmers feel entirely independent, and sell their milk to that dealer who bids the highest price and who offers them the easiest set of sanitary rules. The demand for milk has compelled the large dealers to seek further and further away for their supply and has brought about a competition in the country for the patronage of the farmer, which is just as keen, and in many instances keener, than the competition for the custom of the consumers in the city. For this reason large dealers can exercise only a very limited control over sanitary methods of the dairy farmers, particularly in those regions where competition for the supply is keenest.

When the milk once comes into the hands of the dealer, however, its sanitary surroundings are whatever he chooses to make them. The utmost measures of the dealer are of little avail if the milk placed in his hands by the farmer is already seriously damaged by the advent of dirt and bacteria. It is this fact that has led so many of the large dealers to resort to pasteurization. What they cannot control at the beginning they can at least remedy at the end by the application of a moderate amount of heat.

Certified milk represents the efforts of some physicians to obtain a supply of milk from cows free from disease and produced under sanitary conditions, which will permit it to be marketed in its natural raw state, still having a very low bacterial count. The cattle supplying certified milk are required to pass the tuberculin test. In Brooklyn 2,800 quarts of certified milk are sold daily at 15 cents per quart; in Manhattan and the Bronx 14,000 quarts are sold at prices ranging from 15 to 20 cents per quart.

"Inspected milk" is a second-grade milk designed for hospital use and sold mostly in cans. It is under the supervision of the same Milk Commission which controls certified milk. The bacterial standard and conditions of production are not so severe as for certified milk, and the tuberculin tests of cattle producing it is not required. It sells in cans at 6 and 7 cents per quart. About 5,000 quarts daily are sold in the city. It serves as a good illustration of raw milk of excellent quality which can be sold at moderate prices.

These figures give some idea of the size of the problem confronting those who are interested in the improvement of the milk supply. It at once becomes evident that no private or outside enterprise can do more than serve as an object lesson. Any plans to furnish an improved quality of milk to the city on a large scale and outside of the regular lines of the industry would be foolhardy. The real reform must be wrought from within the industry itself.

colonies counted after growing five days at room temperature.

	Sanitary Barn	Old Barn
1903 September	660	1,950
1903 October	354	331
1903 November	287	425
1903 December	505	457
1904 January	355	1,244
1904 February	1,721	3,910
1904 March	690	4,200
1904 April	3,300	4,600
1904 May	1,950	10,200
1904 June	550	1,900
1904 July	1,260	3,500
1904 August	1,534	4,010
Average for year	1,097	3,102

The extremely small numbers of bacteria in the milk from the old barn were a revelation to me. They indicated plainly the availability of ordinary barns for clean milk production, provided access could be had to a proper sterilizing, cooling and bottling establishment.

Following this suggestion, during the same year, a second old barn still further removed from the dairy was brought into commission. No attempt was made in this instance to change the character of the interior of the building. The ceiling was low, and composed of poles, through which the hay overhead hung down in festoons. The stalls were very crowded and the floors of rough and broken boards. It was just the kind of barn that calls down the severest wrath of dairy experts, and therefore well suited to illustrate the point I desire to emphasize. Appended are the bacteria counts of milk from this building, averaged for a period of four months:

Milk from Second Old Barn.

1904 March	Average bacteria per c.c.	1,920
1904 April	" " " "	6,050
1904 May	" " " "	6,370
1904 June	" " " "	10,530

An analysis of the air in this stable made during milking showed 12,965 colonies of bacteria upon a Petri plate exposed for one minute, while in the same length of time the air of the new sanitary barn showed only 35 colonies. The small number of bacteria in the milk from this old barn were undoubtedly due to the use of covered pails and to the facilities which the dairy house afforded for sterilization of utensils and cooling and bottling of milk.

Early in the autumn of 1904 I directed the attention of Dr. A. H. Stewart, Bacteriologist of the Department of Health in Philadelphia, to the possibility of producing milk with low bacterial counts in common unsanitary cow barns, by the use of sterile covered milk pails and cans. By agreement we arranged to conduct some experiments on dairy farms in my neighborhood, where the sanitary conditions were bad. Following are quotations from Dr. Stewart's paper, "The Contamination of Milk at the Dairy" (*American Medicine*, April, 1906).

EXPERIMENT I—DECEMBER, 1904.

"The experiment was conducted in an ordinary filthy farm stable. The weather was cold, snow was on the ground, and two boys did the milking; there were eight Jersey cows in the herd. No effort was made to cleanse the udders . . . the cattle were fed with dusty hay, as was the custom, during the milking." Four cows were milked in the ordinary wide-mouthed unsterilized milk pails used at the farm. The other four were milked into narrow-mouthed pails carried with us in our buggy. The results of Dr. Stewart's analyses were as follows:

Sterilized Covered Pail

First cow's milk	1,000	bacteria per c.c.	
Second " "	4,900	" " "	
Third " "	500	" " "	
Fourth " "	150	" " "	

Farmer's Own Unsterilized Pail.

First cow's milk	120,000	bacteria per c.c.	
Second " "	140,000	" " "	
Third " "	17,000	" " "	
Fourth " "	138,000	" " "	

EXPERIMENT II, DECEMBER 9, 1904.

"An ordinary dirty barn, with a dark filthy cow stable, was selected for this experiment." Two cows were milked into sterile covered pails and two into the farmer's own, open unsterilized pails. Two cows were milked, first half with covered sterile pails, and the second half into farmer's own pails, to test the effect upon milk of the same cows, of change of pails.

Dr. Stewart's analyses gave the following results:

Sterilized Covered Pail.

First cow's milk	200	bacteria per c.c.	
Second " "	50	" " "	
Fifth " " First half	300	" " "	
Sixth " " " "	120	" " "	

Farmer's Own Open Unsterilized Pail.

Third cow's milk	2,400	bacteria per c.c.	
Fourth " "	34,400	" " "	
Fifth " " Second half	2,000	" " "	
Sixth " " " "	45,690	" " "	

And now in marshaling my array of facts I have arrived at an experience that for my purpose is the most important of all.

The limits of production on my own farm had been reached and still there was demand for more milk. Three and one-half miles from my sterilizing plant lived a well-to-do farmer having a large barn of the better class, containing sixty cows. It occurred to me that though the distance from my dairy house was great, yet milk low in bacteria might be produced on this farm by applying the same principles that had proved efficient in my own old barns. At that time this farmer shipped all of his milk to Philadelphia, and received for it four cents per quart, out of which he had to pay a half-cent per quart for freight. Analyses of his milk showed that it was running several hundred thousand bacteria per cubic centimeter. My offer to him was five cents per quart for his milk, provided he would use my sterile pails and cans, and deliver the milk to my dairy house twice daily. He agreed to the pails and cans but not to the delivery, as the railroad station was close to his farm and he was unused to a long haul. For a period of more than four months thereafter, my wagon went the three and one-half miles to this farm for milk, carrying on each trip a complete sterile outfit for the farmer's use at the next milking.

This herd of cows had been tested for tuberculosis, by the tuberculin test. Daily examinations were made of the milk for bacteria, and the average by the month for the four months of the contract, were as follows:

Milk Delivered From Stable, Three and a Half Miles Distant from Sterilizing and Bottling Station.

1904 September	Average bacteria per c.c.	3,974
1904 October	" " " "	7,892
1904 November	" " " "	2,100
1904 December	" " " "	2,520

The proprietor of the farm often assured me that the additional trouble of milking my way instead of his own was very slight, and that five cents per quart repaid him for this extra care many times over; in fact, at that price he made a profit on his milk, whereas the former price barely paid his expenses.

I was now convinced that this method of milk production could be made to include many farms in my vicinity. My plan was simply to take away from the farmers the whole matter of washing utensils, and to do everything of the sort at my own steam plant, supplying them with sterile milk containers and asking them to bring the milk to me twice daily. A number of farmers in the neighborhood agreed to take part in this scheme. The apparatus and printed bottle caps were completed when disturbance of business conditions prevented us from carrying out the arrangement.

Since the experiences above narrated I tested the same principles again in 1906, with the cooperation of a farmer who was under condemnation by the local board of health in one of the suburban towns. The result was a great improvement in the bacteria counted in his milk, at a very slight expense to him. The experiments of Goler and Roby in Rochester, of Conn at the Storrs Agricultural Experiment Station, of Chapin, Park, Pearson and others, have all gone to show that at a very slight expense in the cow stable, milk with low bacteria count can be produced.

In laying the foundation for the suggestions I have to make regarding milk production, it is necessary to draw attention to another point. During the first two hours after the milk is drawn from the udder of the cow, there is practically no increase in the numbers of bacteria. Some authorities have asserted that this is due to the "germicidal action" of milk; however that may be, the experiments made by a large number of investigators upon milk during the first two hours after it is drawn, without cooling and therefore still containing the animal heat, all go to show that the increase in the numbers of bacteria is very slight, and frequently zero.

It is only necessary to quote the results of a few of these experiments to illustrate this fact. In the annual report of the Storrs Agricultural Experiment Station, 1903-04, is published the result of an investigation of the so-called "germicidal property" of milk, by W. A. Stocking, Jr. Among the results we find these:

Average of 12 milks freshly drawn..	6,832	bacteria per c.c.
" same, after three hours..	6,224	" " "

Again, in another series of tests in the same investigation, we find:

Average of 5 samples of fresh milk..	9,779	bacteria per c.c.
" same after 2 hours.....	9,774	" " "
" " " 4 "	9,813	" " "

In both these series of tests the samples were kept at a constant temperature of 20° C. (68° F.).

Among the many other investigators who have furnished evidence to show the slight increase of bacteria in milk during the first two hours is Dr W. H. Park (*Journal of Hygiene*, July, 1901), in a test of milk kept at a temperature of 90° F., as follows:

Good fresh milk contained.....	5,200	bacteria per c.c.
After two hours.....	8,400	" " "
After four hours.....	12,400	" " "

Freudenreich, Conn, Hunziger, and others have shown that there is only a slight increase, and often a reduction, in the numbers of bacteria in milk during the first few hours after it is drawn, even when kept at comparatively high temperature.

It is these facts that have convinced me that we have in our possession some simple sanitary principles which can be put into operation in connection with the milk supply of New York, and with a very slight readjustment of business conditions.

My proposition, in short, is to elevate the creameries which are now largely used as shipping stations to the position of sterilizing, cooling, and bottling stations, to serve a number, if not all of their farms. Surveying the geography of the milk industry, we find creameries and shipping stations dotted all over the country. They are natural centers of influence in the milk industry. They are naturally adapted to become large sized dairy houses for the cow stables located within an hour's drive. Many of them already contain a steam plant, ice houses, and bottling equipment. Only a slight addition to these would be necessary to enable them to perform the functions of a central dairy house. The plan is in detail as follows:

1. Take the whole matter of washing utensils out of the hands of the individual producer. Concentrate the washing of milk cans, milk pails, etc., in the creamery, where it can be done thoroughly.

2. Insist on the use of some form of covered milking pail. These would preferably be owned by the creamery, and the pails now used by the farmers discarded. Right here I must say that I am indebted to Dr. Roby, of Rochester, for a suggestion that exactly fits into this plan. He recommends a reduction in the number of dairy utensils by substituting small sized milk cans to take the place of both milking pails and the large cans now in use. The farmer can conveniently use a small milk can, both for milking and for carrying his milk to the creamery. A sixteen-quart milk can has a small mouth and is just the correct height from the ground to receive the milk from the cow's udder. Such a can would probably hold the milk from four cows at one milking. When filled, the lid may be firmly fastened in place, and the milk conveyed to the creamery, without the necessity of transferring it to any other form of container.

3. Take all cooling and bottling of milk out of the hands of the farmer. The temperature of the milk delivered by farmers to the creameries, during the warm months, is seldom below 60° F. A cooler of any sort is a dangerous weapon in the hands of the farmer, because of his inability to keep it sterile. The advantages gained by cooling at the farm are lost by the contaminations which occur during the transfer of the milk over cooling apparatus and into several containers. It is a rare thing to find a farmer supplied with ice for cooling, and his common recourse is the brook or spring house, which seldom reduce the temperature of the milk below 60° F. This temperature is not sufficient to prevent the growth of bacteria, which is sure to take place during the twelve hours or more delay to which one of his milkings is subjected before delivery at the creamery. Facilities can be provided for promptly cooling the milk to 40° F., and the creamery is also the natural center for bottling milk. In fact, some of the milk now shipped to New York is being bottled in the creameries.

4. Let the farmer make deliveries of milk to the creamery twice a day, within one hour after milking is completed. Such quick delivery, as has been pointed out, will bring the milk to the creamery in time to forestall any serious growth of bacteria.

5. Let the milk dealer offer financial inducement to the farmer (*a*) for using the small "pailcans," as we may call them; (*b*) for delivering the milk twice daily to the creamery; (*c*) for furnishing milk from tuberculin tested cows. Five cents per quart is sufficient to induce many farmers to produce milk by this method.

6. Let the public offer a financial inducement to the dealer, (*a*) for the slight increase of price he must pay the farmer, and (*b*) for the extra work undertaken by the creamery. Ten cents per quart in the city is, I believe, a price that will prove to be profitable to the dealer for such milk.

In this method of milk production, the sanitary operations are reduced to the very lowest terms. The present method exposes us to all sorts of milk infection. If there are forty farms in a given area delivering milk to the creamery, there are forty kitchens, forty wash tubs, forty sets of strainer cloths, forty sets of milk pails and cans, and forty kinds of water—all these being possible sources of infection. Concentration of all dairy operation at the creamery at once removes all these dangers, and reduces the chances of contamination to those alone which are incidental to the creamery operations. In a well conducted creamery with good water supply and proper sterilizing facilities, the chances for milk infection should be very slight.

I can hear objectors say that conditions in the cow stable should be brought to a higher degree of sanitary perfection. This is certainly true, and is something that we should all strive to accomplish; but let us do first what we can do now; later on we may bring about a more ideal condition. The average farmer is not a sanitarian and he is not a capitalist; we cannot expect him to invest in new buildings or to understand sterilization. Under these circumstances I believe we should relieve him of dairy operations as far as possible, especially of those which he is not well qualified to perform. By the concentration of these in the creamery there would result not only great sanitary improvement, but decided business economy.

The high price of certified milk (fifteen to twenty cents per quart) is chiefly due to the operating expense at the dairy house. The processes of washing, sterilizing, cooling, bottling, refrigerating, and shipping are expensive, and particularly so when done on a small scale. The steam plant, cooling and bottling equipment, etc., on the average certified milk farm, from a strictly commercial standpoint are all out of proportion to the quantity of milk produced on the premises. All of these dairy operations being done on a very large scale, such as would be the case where the creamery was transformed into a dairy house for about forty farmers, would greatly reduce the cost of operation per quart of milk.

A can of milk produced by the method I suggest is not designed to be a substitute for certified milk, or to replace certified milk. The milk produced by this plan could never be so ideal or so perfect as the milk produced upon a certified milk farm or in private dairies.

The point lies just here: the milk produced by common farmers sells in the city for eight or nine cents per quart; and certified milks sell for from fifteen to twenty cents per quart. There is a big gap, both in price and in quality, between the milk as now produced by the ordinary farmer and certified milk. This gap I propose to fill by a method of milk production which is within the powers of the ordinary farmer and milk dealer, and which will send into the market a large quantity of milk of such quality and price, that it will, I believe, prove satisfactory to a large proportion of the public.

I do not flatter myself that any milk dealer will immediately put into practice the suggestions herein made; neither do I imagine that more than a very small percentage of farmers delivering milk to any creamery will consent to the proposition to produce milk in this way; but my experience has taught me that the plan is practicable, and one in which some of the farmers can be interested. I am confident that the method can be started in a small way by any large dealer at his creameries, and gradually extended until a considerable percentage of his milk supply is produced under this system. The sanitary principles and commercial principles involved seem to be the ones along which advance and betterment in milk production can most readily be made.

SUMMARY.

1. The use of sterile covered pails and sterile milk cans by the ordinary farmer will immensely reduce the bacteria in his milk, even though no other sanitary precautions are taken.

2. The dairy house, where washing and sterilizing of utensils and cooling and bottling of milk are done, may be at a distance of several miles from the cow stable without materially increasing the bacterial count, provided the milk is delivered at the dairy house within one hour after milking.

3. Five cents per quart to the farmer will pay him for his trouble of milking in a sanitary way and for making two deliveries a day. In many instances it would compensate him for keeping his herd free from tuberculosis.

4. Increase the functions of the creamery, so that it becomes a washing and sterilizing plant for all the milking pails and milk cans of all the farmers contributing milk to it.

5. Substitute cover milk cans or "pailcans" for the wide-open milking pails now in use.

6. Let the creamery do all the cooling and bottling of milk. Take the cooling out of the hands of the farmer.

7. Let the milk dealer pay the farmer five cents per quart for such milk.

8. Let the public pay the milk dealer ten cents a quart for milk delivered in the city.

9. High prices of certified milk is due to the expense at the dairy house.

10. Concentration of operations at the creamery for a large number of farmers would be business economy, and would likewise eliminate many sources of contamination.

THE IMPORTANCE OF CORRECT DIAGNOSIS IN DISEASES OF THE EYE IS THE CHIEF REASON WHY OPTICIANS SHOULD NOT PRESCRIBE GLASSES.

By A. EDWARD DAVIS, A.M., M.D.,

NEW YORK.

PROFESSOR OF DISEASES OF THE EYE, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; PRESIDENT NEW YORK OPHTHALMOLOGICAL SOCIETY, ETC.

In no branch of medicine is a correct diagnosis of more importance than in diseases of the eye. Not only is this statement true as regards errors of refraction, and local diseases directly affecting the eyes, but indirectly as bearing upon many grave general diseases, as Bright's disease, arteriosclerosis, diabetes, etc., which latter diseases are often first manifested by some disorder within the

eyes. In such cases a correct and early diagnosis of the conditions in the eye and a recognition of their significance as an index of some grave disease, together with the institution of prompt and energetic treatment, all are of paramount importance, if we wish to save the sight of the eyes or the life of the patient.

We will, therefore, in the brief space at our command, consider the subject from two standpoints: First, the importance of correct diagnosis in diseases of the eye and errors of refraction as directly affecting the eye itself and indirectly affecting the general health; and, secondly, the importance of correct and early diagnosis of certain diseases of the eye and a recognition of their value as an index to grave bodily diseases, in which diseases both the sight and life are at stake.

In order to impress upon the profession the great importance of correct diagnosis even in errors of refraction, to say nothing of diseases of the eye, we will, as we proceed, cite some unfortunate cases of mistaken diagnosis which have come under our personal observation, which resulted in much suffering, and, in one instance, hastened the death of the patient.

The importance of correct diagnosis in diseases of the eye and errors of refraction as directly affecting the eye itself, and indirectly as affecting the general health.—It goes without saying that an optician who knows but little or nothing of the structure and physiology of the eye or of the body at large, and their intimate correlations, should not be allowed to decide if a patient (a "customer" in his business) should or should not wear glasses, and if he should require them be allowed to guess what glasses ought to be worn. To make an exact and fair comparison, it would be just as wise to allow the druggist to examine a customer and prescribe some remedy which he thought suitable to the case. The optician should stand in the same relation to the oculist that the druggist does to the physician, that is, he should grind and adjust glasses, following the oculist's prescription, just as the druggist should compound prescriptions as ordered by the physician.

Or, again, to give another comparison strictly on mechanical lines, it would be just as sensible to allow an instrument maker to examine a crippled or deformed child and make and adjust a brace to relieve his condition, without the direction of a surgeon, as to allow an optician to examine a patient's eyes for glasses and adjust them without the prescription of an oculist.

The prescribing optician, opticist, optometrist, or whatever he chooses to style himself, claims that the art of prescribing glasses is strictly a mechanical process and needs no knowledge of the science of medicine. This we deny utterly. But granting, for the sake of argument, that the art of examining the eyes properly and prescribing glasses is strictly a mechanical process, the optician is not adequately trained to do even this.

In order to be able to examine the eyes correctly for glasses requires a knowledge of the use of the ophthalmoscope, and this the optician has not. But to go further and grant that the optician could look into the eye with the ophthalmoscope and estimate correctly upon refractive errors, requiring the use of glasses (which he cannot, as a matter of fact), yet he would be totally unqualified and a dangerous person to undertake such work. The failure of vision might not be due to an error of refraction at all, but to some diseased condition of the eye, and the optician, not having any knowledge of medicine, would be unable to detect the diseased condition, or if he was able to detect it, would not know if it had a bearing on the general health. And herein lies the very great danger of allowing opticians to prescribe glasses.

To give a homely but quite plain example, we might just as well have an untrained and color-blind man take the place of the engineer on a passenger train. Such an individual could not, in the first place, see a danger signal; and in the second place, granting that he was not color-blind, nevertheless, not having had the proper training as to the meaning of the signals, he would yet be a dangerous man to have at the throttle, as he would not know what to do. The danger signals of some general diseases (red hemorrhages, by the way) are often manifest in the eyes long before other symptoms show themselves, and obviously how unjust and criminal in a way, is it to allow unqualified individuals to assume the responsibility in such cases, and thus allow patients to go until it is too late to avert or check the general disease.

Incorrect diagnosis of refractive errors.—Perhaps the most common mistake made in ordering glasses, especially by opticians, is in giving patients minus or negative glasses, where, as a matter of fact, positive or plus glasses should be worn. In other words, hyperopia (far-sight) is mistaken for myopia (near-sight) and minus glasses ordered accordingly. It is unnecessary to say that under the circumstances an extra strain is put upon the eye. And in those cases where there is considerable astigmatism, which is overlooked, or improperly corrected, the strain thrown upon the eye, in the effort to see distinctly, is even greater. This feeling of tension, of drawing, of distress in the eyes, is often referred to as "eye-strain." This so-called eye-strain may produce locally and directly irritation and redness of the eyelids, styes, redness of the eyeball, and intense pain in the eyes and forehead; also, at times, it is thought to produce inflammation in the deeper structures of the eye, as the choroid, retina, optic nerve, and even to hastening the formation of cataract in the aged. Eye-strain frequently is the cause of severe headache, and may, according to some authorities, cause many reflex neuroses, and affect the function of organs far removed from the eyes. Indigestion, constipation, epilepsy, curvature of the spine, and even insanity have been credited to its baneful influence. Be that as it may, what we wish to make plain here is, that the examination of the eyes to decide if glasses are needed, and if needed, the correct lens to prescribe, are no light matters, and should never be undertaken by an optician. Only a physician, and one who has been specially trained for such work (an oculist) should attempt to make a diagnosis of refractive errors and prescribe glasses. For, as pointed out above, the optician who is ignorant of the structure of the eye, not only often gives incorrect glasses, thereby causing much distress, to say nothing of much unnecessary expense to the patient by frequent changing of the glasses; but, because of his limited knowledge and inability to use the ophthalmoscope, fails to detect diseases within the eye, which may be the cause of the failing vision that prompts the patient to seek relief. How very, very important a correct diagnosis is in all such cases must be apparent even to the layman. Quite recently I had a patient (Mrs. E. S.) under my care, who had had her glasses changed a dozen times within a year by an optician, un-

necessarily as it turned out, as she had senile cataract forming in each eye. No actual harm was done in this case, save to putting the patient to much useless expense.

But the disease may be much more serious, as glaucoma, and cause complete blindness, if not detected early and treated, and even then the sight is often lost. I have known of cases of glaucoma to be fitted with glasses by an optician and the vision allowed to become almost totally destroyed before the proper advice was sought, when it was too late.

Again, the diseased condition of the eye causing the poor vision may be but a local manifestation of a grave bodily disease, as Bright's disease, diabetes, arteriosclerosis, etc., and only a trained physician is capable of detecting and knowing the significance of such changes within the eye. Not infrequently he detects such changes in the eye in the early stages of the general disease, and makes a diagnosis even before the family physician, and often when the patient never suspects any serious trouble, thinking that he only needs glasses.

And this brings me to a consideration of the second division of my paper:

The importance of correct and early diagnosis of certain diseases of the eye and the recognition of their value as an index to grave bodily disease.—I shall content myself in the discussion of this portion of my paper by reporting two concrete cases, which will speak more impressively than any abstract statement of facts however true they may be.

Case I.—Within the year, May 13, 1907, a young man, L. D., aged nineteen, consulted me on account of almost total loss of vision. The patient gave a history of having consulted an optician, in September, 1906, because of poor vision in the left eye and constant headaches. The optician examined him, told him his trouble was due to "weakness of the focusing muscle," and all that he needed was a pair of glasses, which the optician gave. Although the glasses proved unsatisfactory, the patient persisted in wearing them, as the optician assured him that he would be all right just as soon as his "weak focusing muscle" gained its strength. In the meantime the patient was fed freely with heavy meats, in order to make him gain strength, which was exactly opposite to what he should have had. When he consulted me in May, 1907, I found a marked albuminic neuroretinitis in each eye, there being marked swelling of the optic nerves, numerous retinal hemorrhages, and many white spots of fatty degeneration in the retina. In other words, to the trained observer, who could see and know the meaning of such changes, it was a typical case of retinitis of Bright's disease. What would have been ludicrous in this case, had it not been so tragic, was that the optician examined the patient just before he came under my care, pretended to use the ophthalmoscope, and pronounced the case one of "syphilis of the eye," although the patient had not a symptom of syphilis. Since "weakness of the focusing muscle" would no longer account for the serious condition of this patient the optician thought he would give him something indeed to account for it.

Although this patient was immediately placed on the proper treatment, it was too late, and he died July 8, 1907, just ten months after first consulting the optician.

Case II.—N T., aged forty-three, a prominent man in this city, consulted me first in February 22, 1903, at which time I examined his eyes and prescribed glasses, his vision with the glasses being normal, and the eyes were sound and healthy. December 2, 1907, three and one-half years later, this patient consulted me for a change of glasses, his right eye especially bothering him. He had no headaches and was apparently in perfect health. In testing him the second time for glasses, while making the examination of the fundus of the eye with the ophthalmoscope, I noticed the characteristic white stippling in the retina of each eye which is often present as a forerunner of Bright's disease. This patient's vision was but slightly reduced in the right eye, and was perfect in the left eye, and when I told the patient that I suspected Bright's disease, he simply laughed and ridiculed the idea, and said it couldn't be so, as he never felt better in his life and did not have a pain or ache of any kind. It was with some difficulty that I had him send a specimen of urine to the laboratory. The examination of the urine showed the presence of albumin and casts in the urine and unmistakable signs of interstitial nephritis. With proper diet, treatment and hygienic surroundings, this patient's life should be prolonged for years. How different the prospect had he fallen into the hands of our friend the optician.

In order to prescribe glasses intelligently and correctly, it is necessary not only to make a correct diagnosis of the error of refraction but to be able to detect or exclude the presence of disease within the eye. The optician is not qualified to do either the one or the other. His sins of commission made in prescribing incorrect glasses in errors of refraction, thereby causing much unnecessary suffering and injury to the sight, are surpassed only by his sins of omission in failing to detect diseased conditions within the eyes, thus allowing the patient's sight to be lost and even life itself sacrificed by his ignorance.

Correct diagnosis is the first and most important factor in the treatment of errors of refraction and diseases of the eye, and physicians only should be allowed to examine or test the eyes for glasses.

PHTHISIS IN OUTDOOR AND INDOOR LIFE AND IN ISOLATED AND COSMOPOLITAN RACES.

By NORBURNE B. JENKINS, M.D.,

NEW YORK.

While outdoor life may cure consumption in the individual, it may lead to susceptibility to tuberculosis in the race, for North American Indians and members of other outdoor races when exposed to civilization are unable to resist the disease.

On the other hand, while indoor life may cause tuberculosis in the individual, it may tend to immunize the race, for Jews and members of other indoor races have marked resistance to consumption. Possibly in time indoor life will eliminate tuberculosis by destroying the susceptible and selecting the adaptable to indoor environment, and thus humanity may be finally immunized not only against consumption, but also against other infection.

Indoor races, in centuries of environment favorable to tuberculosis, in order to survive have probably acquired especial aggressiveness against or resistance to the disease. This immunity has been acquired, since individuals and finally races, favored through variation and by heredity with resistance would escape or overcome the disease and in turn

leave more strongly immunized offspring as racial survivors. On the other hand, individuals without resistance to the disease would tend to perish without offspring, thus eliminating the susceptible. Chinese have been long indoors and have much tuberculosis, but their unfavorable environment rather than lack of immunity seems to account for this, and any other race, however immune, if placed in such environment, would probably have widespread tuberculosis. China, with plenty of food and favorable indoor environment for her people, might become comparatively free from tuberculosis.

In centuries of indoor contact with tuberculosis, phagocytes, enzymes, and opsonins may have acquired power or become trained to resist and overcome the disease. Again, the body may have selected superior tissue or certain as yet undiscovered bactericides with which to resist or arrest the disease. Such means of defense would be transmitted to the body's offspring, and thus not only the body itself but also its successors would survive even in the unfavorable environment of indoor life.

Outdoor races in their natural environment probably escape tuberculosis without the especial resistance which indoor peoples require in order to survive contact with tuberculosis in indoor life. The agents which destroy, expel, transfer, or absorb the *Bacillus tuberculosis* may be partially or entirely absent, may be latent or rudimentary, may be in inherent or acquired weakness from centuries of nonuse or may be unable to combat unaccustomed infection and, in confusion or weakness, are inactive when tuberculous invasion occurs. Outdoor races, when in unchanged environment and at the same time exposed to the *Bacillus tuberculosis*, may resist the disease more successfully than when exposed to both the disease and the more or less unaccustomed environment of civilization.

Biologically speaking, in tuberculosis of immune races, pulmonary structure and function, as well as the agents which dispose of the *Bacillus tuberculosis* and complicating or parasitic bacteria, may be in unfavorable variation, in arrest of evolution, or in reversion; and while such changes may allow invasion, they may result from disuse, tuberculosis or other disease. In suitable environment variation would probably tend to evolve to the normal type and arrested evolution or even reversion might return to the original type.

Race isolation, common in outdoor peoples, may be the chief cause of racial tuberculosis. Segregated races when exposed to the diseases of other peoples are appreciably susceptible. Billings' statistics, U. S. Census, 1890, show that reservation Indians have proportionately more than one hundred times as much tuberculosis as wealthy Jews, but the latter may have more tuberculosis than these statistics indicate. While the races of men in America differ in immunity the Jew and the Indian represent the extremes and are here considered. Jews have been long accustomed to all manner of contact with diseases of civilization, and have probably developed a natural immunity against tuberculosis and other infection. They have been scattered all over the earth, but, owing to the racial exclusiveness of the women, have not been appreciably amalgamated within, therefore the race has not acquired susceptibility from other peoples. As a consequence, the law of the survival of the fittest has had the greatest opportunity to make them the most immune of peoples. Other races after generations in civilization will probably more slowly acquire equal immunity.

The unhappy mental changes resulting from changed environment undoubtedly play a part in tuberculosis in foreigners and in Indians and other wild or semi-civilized races of men, as it does in animals in captivity. This psychological factor, though neglected, is entitled to prime consideration. In civilization many of the instincts and functions and structures of the body and mind of the Indian are in disuse and become susceptible to disease. On the other hand, the Jew has been so long indoors that these susceptibilities, superfluous in civilization, have been eliminated. Centuries of natural selection have fitted the Jew for the indoor environment of cosmopolitan civilization, while, on the other hand, by the same law the Indian has been fitted for an environment of isolated savagery.

Application of the law of the survival of the fittest to tuberculosis has been the aim in writing the above. Perhaps the law of the survival of the fittest was first explained by William Charles Wells, M.D., who was born in Charleston, South Carolina, in 1757. In a paper setting forth the causes of the differences in color and form between the white and negro races of men, read before the Royal Society in 1813, the theory of natural selection as accepted by science of to-day was given to the world by Wells. While indispensable amplification and application of Wells' theory may be found in the writings of subsequent genius, the thought and language of the giant intellect of Wells has seemingly not been improved upon nor simplified, even after a century.

Draining Circumscribed Abscesses of the Pancreas.—Brewer has found the following method suitable for such cases: The following method was employed: A median incision, about 10 cm. in length, was made through the left rectus muscle, and the abdomen opened. The transverse colon with its mesentery was turned upward, and the body of the pancreas palpated through the transverse mesocolon. As soon as the indurated area was appreciated, the intestines were walled-off by gauze-pads, and an exploring needle plunged through the inferior layer of the mesocolon into the center of the mass. A syringeful of creamy pus was withdrawn, and the needle opening cautiously enlarged by introducing a closed pair of thin-bladed dressing forceps and withdrawing them partly opened. About two ounces of pus were evacuated and the cavity syringed out with peroxide of hydrogen. A long, rubber drainage tube, 15 cm. in diameter, was then introduced into the small opening and tightly packed about with a thin strip of folded gauze tape, to prevent leakage of the pus along the side of the tube. The tube and gauze packing were then secured in place by a single stitch of plain catgut. The distal extremity of the gauze tape and the long drainage tube were then brought out, at the lower angle of the wound, leaving ample space for the transverse colon and small intestines to fall into their accustomed places, and form adhesions around the 25 or 30 cm. of the drainage tube, which passed from the abscess to the lower angle of the cutaneous wound. After cleansing the contaminated area of peritoneum, the external wound was tightly closed around the tube and tape by layer suture, and a sterile dressing applied.—*Surgery, Gynecology, and Obstetrics*

Bleeding Hemorrhoids.—Chloride of calcium is recommended by Boas as a hemostatic in this condition. Every morning after the bowels have moved 20 c.c. of a 10 per cent. solution of this agent is injected into the rectum and retained for a little time. If the tendency to hemorrhage is pronounced a second injection should be made at night. If the drug is not chemically pure it may produce burning, pain, and tenesmus.—*Therapie der Gegenwart.*

CONSUMPTION AND SANATORIA.

A VERY important report has been issued recently by the medical department of the British Local Government Board on "Sanatoria for Consumptives and Certain Other Aspects of the Tuberculosis Question." Dr. Timbrell Bulstrode, one of the medical inspectors to the board, is responsible for the compilation of the report, which was begun in 1902. The result of his labors is a movement of careful investigation, and one which may cause our comprehension of tuberculosis to differ somewhat from the views now generally held.
